Abstract

Background: Digital health interventions incorporating self-management strategies are increasingly used to support individuals in managing depression. These interventions often leverage self-monitoring and passive sensor-based data collection to provide personalized feedback, guiding behavioral change. With the proliferation of smartphones and wearable devices, there is growing potential to continuously collect behavioral and physiological data. However, a major limitation in the field is the lack of consolidated evidence on which specific parameters are most useful for monitoring and predicting depression-related outcomes.

Objective: This scoping review aims to identify and synthesize common digital phenotyping and self-report parameters for monitoring and predicting depression. Specifically, it addresses the methodological and knowledge gap concerning which types of sensor-based and self-reported data are most frequently used and which demonstrate predictive value in tracking changes in depressive symptoms across digital platforms.

Methods: A literature search was conducted across 4 databases, including PubMed, Embase, Cochrane Library, and the Web of Science Core Collection. Articles published between January 1, 2021, and November 26, 2025, were included. Eligible studies included adults (≥18 years) with depression confirmed through validated clinical measures and using digital approaches that collected passive sensor data, self-reports, or both. Studies focusing on comorbid disorders, nondigital interventions, or not reporting depression-related outcomes were excluded. The PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines were followed, and a 5-stage methodological framework for scoping reviews was implemented. Quality assessment was performed using the Downs and Black Instrument and the Mixed Methods Appraisal Tool (MMAT).

Results: Nineteen studies were included, comprising a total of 85,193 participants. Most studies used smartphone- or wearable-based tools, with passive sensing as the predominant data source and Patient Health Questionnaire-9 (PHQ-9) as the most commonly used depression measure. Five overarching parameter categories were identified: (1) physical activity and location, (2) behavioral patterns, (3) physiological signals, (4) sleep indicators, and (5) sociability and self-reported assessments. Within these categories, 11 metrics, including step count, heart rate variability, sleep duration and mood self-ratings, were most frequently reported. Most studies used a multimodal digital phenotyping approach, integrating passive sensor-derived data with active user-reported input, enabling more individualized symptom monitoring over time.

Conclusions: This scoping review provides a novel synthesis of common digital parameters used across diverse tools for monitoring and predicting depression, moving beyond tool- or modality-specific perspectives adopted in prior reviews. Unlike existing reviews focusing on individual sensing modalities, prediction methods, or intervention effectiveness, this review maps shared parameters across observational, predictive, and interventional studies. By identifying convergent digital markers, the review supports comparability across studies and informs future model development. These findings have practical implications for the design of scalable digital mental health tools and for translating digital phenotyping into real-world clinical and self-management contexts.

KEYWORDS

depression; digital phenotyping; sensor data; objective data; self-monitoring

Introduction

Advancements in personal digital devices and sensor technologies have enabled continuous and unobtrusive data collection from individuals in real-world settings, expanding the possibilities in health care data management [1]. This has given rise to digital phenotyping, defined as the moment-by-moment quantification of individual-level behavior and aspects of physiology using data from personal smartphones and wearable devices of users [2].

The sensors commonly embedded in these devices can be broadly categorized into (1) motion sensors, (2) location sensors, and (3) environment sensors [3]. More specifically, smartphone-based sensors include linear acceleration, rotation vector, humidity, orientation, gravity, magnetic field, accelerometer, ambient temperature, gyroscope, light, pressure, microphone, proximity, and others [4]. Each device uses multiple sensors working together to provide optimal output for the user. For instance, environmental sensors, including humidity, illumination intensity, surrounding pressure, and temperature sensors enable automatic smartphone screen brightness adjustment or calculation of the dew point for the day [3]. Similarly, the geomagnetic sensor and accelerometer show user-relative location to the North Pole, providing basic data for location sensors. Motion sensors assess acceleration, speed of revolution, gravity, curl vector values, and drift, allowing tracking of multiple motions of the user, such as car direction (eg, navigation application), steps walked (eg, fitness or exercise mobile applications), and speed of movement (eg, user car speed) [3,5].

Unobtrusive tracking of health data relying on physiological parameters such as heart rate, step count, sleep, and others commonly occurs by using sensor fusion (ie, putting multiple signals together) [6]. For instance, biosensors can track physical parameters such as heart rate [7], while location sensors can disclose patient activity and potentially help infer how often outdoor activities occur, which is particularly important for individuals living with mood disorders such as depression [8]. Social patterns can be monitored through the aggregated amount of mobile phone calls and textual messages exchanged with others, pointing to social activity or potential social withdrawal, often serving as an indicator of a depressive episode [9]. Finally, sensor fusion can be used by combining multiple sensors such as accelerometer, ambient light, battery level, microphone, phone lock status, phone unlock status, and screen status for the physiological parameter of sleep that has a significant role in indicating depressive episodes [10].

Some of the earlier works that explored the field of digital phenotyping in mental health include a systematic review [11] of smartphone-based passive sensing, summarizing common data sources such as GPS, accelerometry, and phone usage metrics. Several research papers have outlined the promise of personal sensing approaches in psychiatry while also emphasizing challenges related to data interpretation and real-world implementation [12,13]. Early empirical support for the clinical relevance of smartphone-derived data has been demonstrated through significant correlations between sensor-based measures and depressive symptom severity [14].

Recent reviews have demonstrated growing interest in the use of passively collected data for depression monitoring, reflecting the rapid advancement of digital phenotyping approaches. For example, several studies have focused on specific technologies, such as smartphone-based sensing alone, or emphasized algorithm development for symptom detection rather than broader clinical integration [15-18]. Others have targeted a narrower set of parameters [19], which limits their scope for cross-study synthesis. In contrast, the present review aims to provide a comprehensive overview of the parameters most commonly used in digital interventions for depression, regardless of delivery platform, by synthesizing data across smartphone- and wearable-based sensing studies. This broader focus is intended to support standardization efforts and inform the development of more effective and clinically relevant digital mental health tools.

There is a considerable variability in the types of parameters used, the degree of personalization, and the delivery modes, making it difficult to compare studies or determine which features are most effective [19-22]. This lack of consistency makes it difficult to develop reliable digital health tools. Moreover, health practitioners and end users often lack clear guidance on which digital tools offer meaningful and reliable support.

To address such gaps, this review aims to map the landscape of passively collected parameters used in digital interventions for depression, with the goal of informing future research, standardization, and clinical application.

This review is guided by the following research questions:

1. What passively collected parameters are commonly used in digital interventions for depression to support longitudinal monitoring of depressive symptoms?
    - Which types of passively collected data are used?
    - Which parameters are most frequently used?
    - Which parameters have demonstrated predictive value for changes in symptom severity?

We define a parameter as any sensor-derived measure used to monitor or predict depression-related outcomes.

Methods

Study Design and Framework

This scoping review was conducted in accordance with the 5-stage methodological framework for scoping reviews, including (1) identifying the research question, (2) identifying relevant studies, (3) study selection, (4) data charting and synthesis, and (5) collating, summarizing, and reporting results [23]. The data were systematically collected and reported by

XSL•FO
RenderX

following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines (Checklist 1) [24].

This scoping review was not registered in PROSPERO (International Prospective Register of Systematic Reviews), as PROSPERO does not accept registrations for scoping review protocols at the time of this writing.

Data Sources and Search Strategy

We conducted a comprehensive search of 4 electronic databases, including PubMed, Embase, Cochrane Library, and Web of Science Core Collection. Study registries were searched, including ClinicalTrials.gov and the World Health Organization International Clinical Trials Registry Platform (WHO ICTRP). The findings from these registries are categorized under "Others" in the PRISMA flow chart. No online or print sources were purposefully searched or browsed outside of the 4 electronic databases. No table of contents, conference proceedings, organizational websites, or print materials were hand-searched for this review. However, reference lists of included articles were also manually screened to identify additional eligible studies, which are categorized under "Other" in the PRISMA flow chart. No databases were searched simultaneously on a single platform, and no additional studies or data were sought by contacting study authors, experts, manufacturers, or others.

Studies published between January 1, 2021, and November 26, 2025, were included to reflect the recent advancements in digital phenotyping and mobile sensor technology in mental health. Our searches applied limits for publication date and language. All searches were last conducted on November 26, 2025 across all included databases, restricted to publications in English or German. These limits were used to ensure that the review captured the most current developments in digital interventions and digital phenotyping, as the technological landscape in this field evolves rapidly. No additional limits (eg, study design filters) were applied. The searches were updated manually by rerunning all database queries prior to final analysis. No automated alerts, citation tracking tools, or continuous updating services were used. The search strategy combined controlled vocabulary where applicable (eg, medical subject headings [MeSH] in PubMed) and free-text terms related to depression, digital health interventions, sensor data, and digital phenotyping. No published search filters were used for this review, and no search strategies from previous literature reviews were adapted or reused. All search strategies were developed manually using combinations of keywords and medical subject headings relevant to depression, digital phenotyping, and digital health interventions. The search strategy did not use any existing validated filters (eg, clinical study filters or methodological filters). No formal search peer review process was conducted for this review.

A summary of keyword combinations is provided in Table 1. For detailed search strategy see PRISMA-ScR Checklist 1 containing a detailed search strategy across databases.

A total of 3243 records were identified during the study selection process, screened (n=1406), and reviewed for eligibility (n=134). After applying inclusion and exclusion criteria, a total of 19 studies were included in the final analysis. Reasons for exclusion included studies without digital interventions, nonclinical populations, and studies focused on comorbid conditions or unrelated mental health disorders.

The total number of records identified within each database and other information sources was 3243 (PubMed n=518; Cochrane Library n=1256; EMBASE n=791; Web of Science n=276; and Others n=402). Relevant records were identified from 4 databases (n=518) and clinical trial registers (n=2725). After duplicate removal, 1406 records were screened. Following full-text screening and exclusions, 19 studies were included in the final review. Common reasons for exclusion included lack of intervention focus (n=27), nonclinical populations (n=13), or nondigital approaches (n=9). Records retrieved from all databases and clinical trial registries were exported into Microsoft Excel and manually reviewed to identify and remove duplicates. Deduplication was performed by comparing study titles, authors, publication years, and digital object identifiers. No automated or software-assisted deduplication tools (eg, Covidence [Veritas Health Innovation] or EndNote [Clarivate]) were used.

Eligibility Criteria

Studies including randomized controlled trials, observational studies, and mixed method primary studies were considered. Eligible studies include digital health interventions for adults (≥18 years) concretely addressing depression that is assessed primarily with clinical measures such as the Patient Health Questionnaire-9 (PHQ-9) or similar validated instruments. The population focus is mainly on participants that, at the time of study participation, were experiencing depression, noted with a clinical measurement tool and digital phenotyping methodology. Study reports on outcomes related to the assessment of digital phenotyping for depression or dedicate a substantial amount of work to such reporting. The timeframe for published studies was limited from January 1, 2021 to November 26, 2025 to capture the most recent advances in digital phenotyping and mobile sensor monitoring in mental health. This period marks a notable shift from early feasibility and pilot work to more sophisticated methods, including multisite validation, machine learning–based prediction models, and integration of wearables and smartphone sensors [25]. By focusing on this timeframe, we ensure that the review remains aligned with current technological capabilities and clinically relevant research directions.

XSL•FO
RenderX

Study Selection

Title and abstract preselection was performed by 2 authors LB and MP. Screening questions included:

1. Does the study use a digital intervention for depression delivered via a digital tool (eg, mobile app, wearable, web-based platform)?
2. Does the study report on depression outcomes assessed through clinical instruments and/or digital phenotyping?

Relevant studies were retrieved and screened in full text by one author LB. After removing duplicates, LB, MP, and RA cross-checked the full texts against the inclusion and exclusion criteria. UH served as a supervisory reviewer. In an online meeting, final study selections were presented by LB and MP, who provided justification for inclusion decisions to UH.

Inclusion Criteria

Studies were included if they met the following criteria:

1. Examined a digital intervention aimed at monitoring or improving depressive symptoms
2. Delivered via smartphone apps, wrist-worn devices, web-based platforms, offline software, or automated interactive voice response systems
3. Included adult participants (≥18 years) with depression, confirmed through validated clinical instruments (eg, PHQ-9)
4. Reported on outcomes related to monitoring and/or symptom improvement using digital phenotyping (passive sensor data and/or active user input)
5. Provided data on device use (eg, number of interventions delivered, duration of engagement)
6. Published in English or German, and accessible via open access or institutional access.

Exclusion Criteria

Studies were excluded if they:

1. Focused on depression comorbid with other conditions (eg, cancer, substance use, pregnancy, or other mental health disorders)
2. Focused on depression in the context of a viral pandemic (eg, COVID-19)
3. Studies use or report on depression based on digital interventions aimed at supporting and improving physical activity [26].

Analysis Approach

Data Extraction, Charting, and Synthesis

A structured Microsoft Excel form was developed by the author LB to extract key information from each included study. Extracted variables included:

- Study characteristics (author, year, and country)
- Participant demographics and sample size
- Type of digital intervention and delivery platform
- Sensor types and data collection methods
- Depression assessment tools (baseline and follow-up)
- Frequency and duration of interventions
- Outcomes related to depression monitoring or prediction

Once data were initially charted, it was presented in an online meeting to co-author MP and cross-checked among author LB and co-author MP. For more detailed procedures for selection of the studies, extraction, and exclusion, please see Multimedia Appendix 1.

Due to heterogeneity in study design and reporting, a narrative synthesis approach was used. Data were charted and grouped into thematic categories of parameters (see Table 2), including physical activity and location, behavioral patterns, physiological signals, sleep indicators, and sociability and self-reported input.

Table . Overview of the retrieved studies in terms of data collection method, type of digital tool, depression measures, main findings, and predictive value for depression reported.

Study ID	Reference identifier	Sample size (depression)	Data type	Digital tool type	Depression measure	Main findings	Predictive value reported
1	[27]	313	Passive + Active	Smartphone app, wearable	PHQ-9[a]	Multiple behavioral and phone use features significantly correlated with PHQ-9	Yes
2	[28]	400	Active	Computer	PHQ-9	Behavioral test metrics significantly predicted depression	Yes
3	[29]	290	Passive	Fitbit	PHQ-9	Variations in heart rate and circadian rhythm linked to depression	Yes
4	[30]	92	Passive	Smartphone app	PHQ-9	User engagement is essential for data reliability	Unclear
5	[31]	81277	Active	Smartphone app	PHQ-9	Minimal average usage; thought diary and tests most used	No
6	[32]	934	Passive	Smartphone app	PHQ-2[b]	Weak correlation between keystroke timing and symptoms	No
7	[33]	65	Passive	Smartphone app	CES-D[c]	Subject-specific standardization improved forecasting	Yes
8	[13]	60	Passive + Active	Smartphone app, Oura Ring	DASS-21[d]	Best prediction from combined smartphone + wearable + mood	Yes
9	[34]	28	Active	Computer	PHQ-8[e]	Digital social rhythm therapy improved depression	Yes
10	[35]	614	Passive	Smartphone app, Fitbit	PHQ-8	Lower engagement correlated with higher depression	Unclear
11	[36]	1	Passive	Smartphone app, wearable	Not stated	Demonstrated potential of ambient light and usage data	Unclear
12	[37]	18	Passive	Video assessment	MADRS[f], MINI[g], CSSRS[h]	Facial and speech features correlated with MADRS	Yes
13	[38]	20	Passive + Active	Smartphone app, wearable	MADRS, HDRS[i]	Self-report had higher predictive correlation than passive sensors	Yes

XSL•FO
RenderX

Study ID	Reference identifier	Sample size (depression)	Data type	Digital tool type	Depression measure	Main findings	Predictive value reported
14	[39]	623	Passive	Smartphone, Fitbit	PHQ-8	Sleep timing features correlated with depression severity	Yes
15	[20]	107	Active	Smartphone app	PHQ-9	Web-based support linked to symptom improvement	Yes
16	[40]	43	Active	Smartphone app	BDI[j]	Smartphone mood ratings correlated with standard assessments	Yes
17	[41]	48	Passive + Active	Smartphone app, wearable	PHQ-9	Higher engagement led to greater symptom improvement	Yes
18	[42]	136	Active	Smartphone app	BDI-II[k]	Significant treatment-related symptom changes	Yes
19	[43]	124	Active	Computer	DASS-21	Personalized feedback led to greater symptom reduction	Yes

[a]PHQ-9: Patient Health Questionnaire-9.

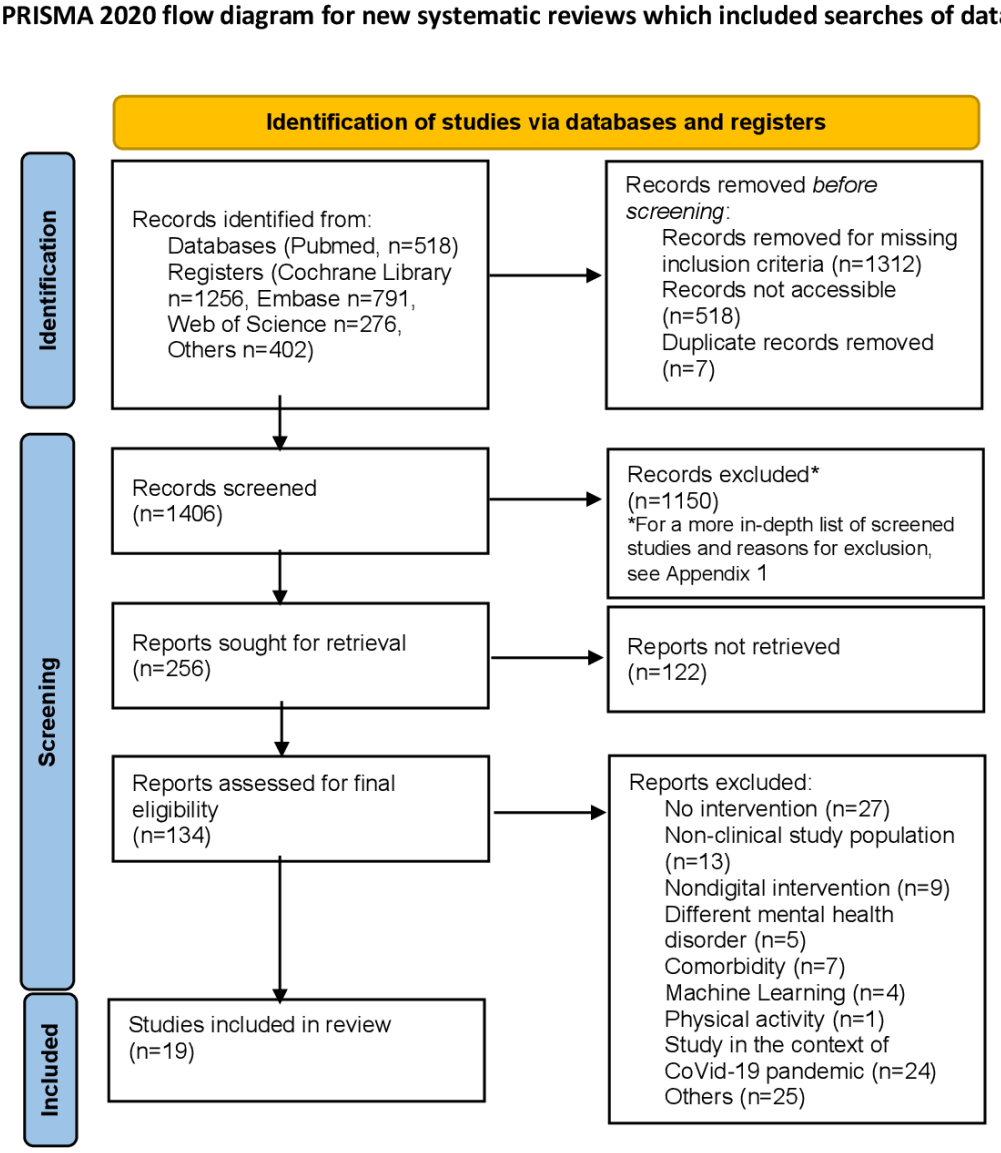
[k]BDI-II: Beck Depression Inventory, Second Edition.

The frequency of each parameter category and its reported predictive value were also noted.

Quality Appraisal

To assess the quality of the included studies, we used two tools, including (1) the Downs and Black checklist [44] used for randomized controlled trials and quantitative studies and (2) the Mixed Methods Appraisal Tool (MMAT) [45] used for mixed method and nonrandomized studies.

These complementary tools allowed a consistent evaluation of methodological rigor across diverse study designs. Detailed quality assessments are included in Multimedia Appendices 2-4.



Results

Summary of Included Studies

A total of 19 studies [13,20,27-43] with 85,193 participants across studies were included, covering a diverse range of digital intervention types and data collection methods. The study selection process is shown in Figure 1.

XSL•FO
RenderX

Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) flow diagram of the study selection process. Diagram adapted from PRISMA-ScR guidelines [24].

Most digital tools or platforms (n=15) used smartphone apps, either alone or in combination with wearable devices (eg, Fitbit [Fitbit, Inc], Oura Ring [Oura Health Oy]). Three studies (16%) used computer-based platforms, and one used a computer-based platform for video-based digital phenotyping. The included studies varied greatly in design and measurement approaches (see Table 3). The majority were observational studies (n=14), including cross-sectional, longitudinal cohort, retrospective, interformat validation, and feasibility designs, while 5 studies delivered a digital mental health intervention [20,34,41-43]. Three studies were randomized controlled trials [13,42,43], and 2 used a retrospective observational approach [30,39]. Several observational studies used repeated-measures designs to monitor depressive symptoms over time, although study duration and assessment frequency were heterogeneous. One study collected single-participant feasibility data [36], while another followed participants longitudinally for 43 weeks [35].

XSL•FO
RenderX

Table . Description of study design, subtype, number of studies included, and reference number.

Study design and subtype (if applicable)	N	Reference number

Data Collection Approaches

Three data collection types were noted, including passive data collection, active input, self-reports, and multimodal approaches, which combined both passive and active inputs.

Passive data collection (eg, from GPS, accelerometer, and heart rate sensors) was used in 84% of studies (n=16).

Active input and self-reports (eg, mood ratings, diary entries) were used in 58% of studies (n=11).

Multimodal approaches combining both passive and active inputs showed the highest predictive potential and were used in 47 % of studies (n=9).

Clinical Measures Used Across Studies

Validated tools used across studies included Patient Health Questionnaire versions 9, 8 and 2 (PHQ-9, PHQ-8, and PHQ-2), the Center for Epidemiologic Studies Depression Scale (CES-D), the Depression Anxiety and Stress Scale (DASS-21), the Beck Depression Inventory original and revised version (BDI-I and -II), the Montgomery-Åsbergg Depression Rating Scale (MADRS), the Hamilton Depression Rating Scale (HDRS), and the Mini-International Neuropsychiatric Interview (MINI), reflecting a broad clinical foundation across studies (see Table 2).

The PHQ-9 was the most used depression measure, used in 9 studies. The second most used depression measure included PHQ-8 (studies n=3) [34,35,39] while PHQ-2 was used in only one study [32]. Other often used measures were DASS (studies n=2) [13,43], MADRS (studies n=2) [37,38], MINI. (studies n=2) [37,38] and HDRS [38] used in only one study.

Predictive Value

Of the 19 studies, 15 (79%) [13,20,27-29,33-35,37-43] reported predictive or diagnostic associations between digital parameters and depression outcomes. Predictive value was strongest in studies that:

1. Incorporated multisource data fusion [9,13,38]
2. Applied machine learning or modeling techniques for forecasting [28,33].

Sensor Types and Platforms Breakdown

Across the reviewed studies, most digital interventions assessed or observed relied on smartphones as the primary platform, often enhanced with wearable devices (eg, Fitbit, Oura Ring) for additional collection of physiological data.

The most frequently used sensors included accelerometers, gyroscopes, GPS, light sensors, and microphone sensors.

Wearables primarily contributed heart rate and sleep cycle data, while smartphones captured mobility, screen interaction, ambient context, and social communication metrics.

Only a few studies [28,37] used computer-based platforms or video-based assessments, which focused on cognitive tasks, facial expressions, and speech expression as digital biomarkers.

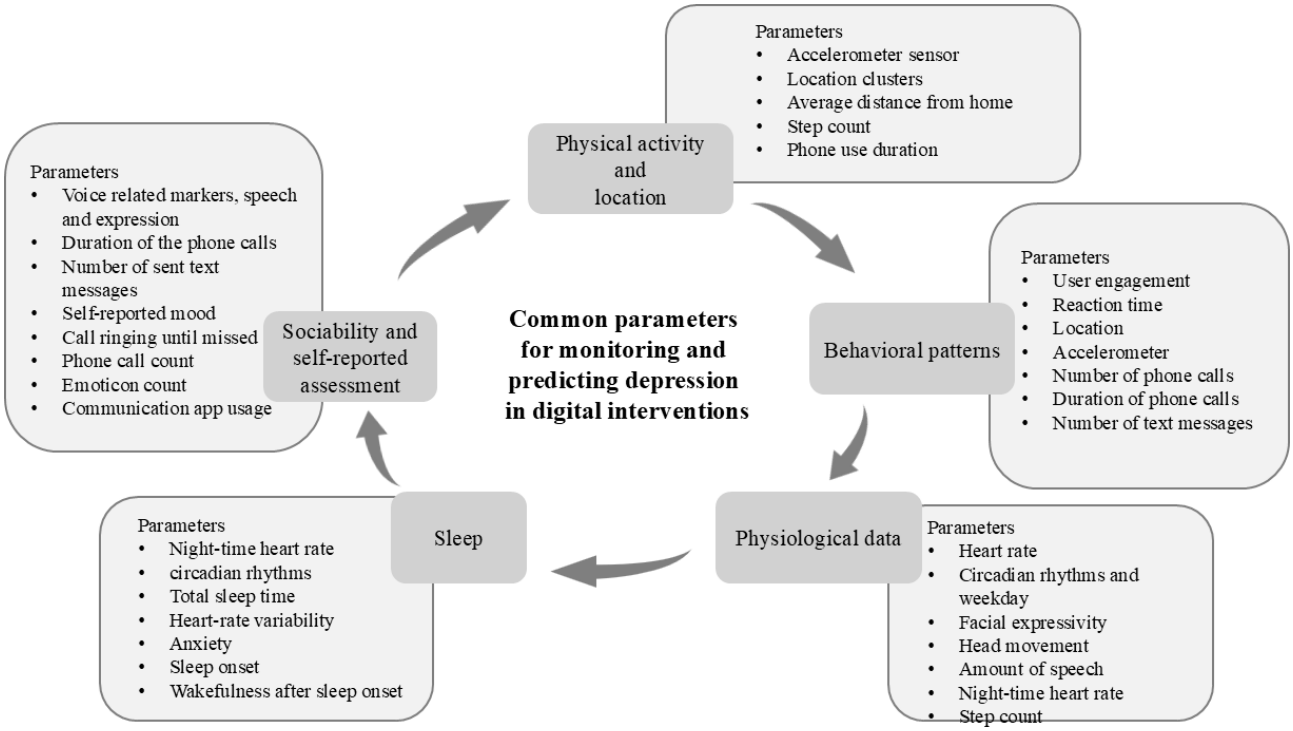
Across retrieved studies the most common device used for digital data collection was a smartphone (n=13), while wearable devices such as sensors and other wrist-worn devices (eg, Fitbit) were used in 8 studies. A detailed list of devices with the main findings reported can be seen in Table 2.

Key Findings

The key findings were grouped into five major categories of passively collected parameters: (1) physical activity and location, (2) behavioral patterns, (3) physiological data, (4) sleep, and (5) sociability and self-reported assessments (see Table 2 and Figure 2). Table 2 summarizes the most commonly used passively collected parameters in digital interventions for depression. Sleep-related parameters such as total sleep time, sleep onset, and heart rate during sleep were particularly prevalent, often inferred through sensor fusion.

Similarly, physical activity metrics like step count and accelerometer data, along with location tracking (eg, distance from home), were commonly used to assess daily functioning and routine stability.

Sociability parameters, including phone call frequency, text message frequency, and app usage, were often used to approximate social withdrawal.



Behavioral data like reaction time or user engagement further contributed to characterizing depressive symptomatology. Figure 2 illustrates how these domains interconnect and highlights their contribution to monitoring and predicting depression.

XSL•FO
RenderX

This multidomain structure, used in 47% of studies, supports a more concrete understanding of symptom trajectories and lays a foundation for developing more reliable personalized digital interventions that incorporate digital parameters.

1. Physical Activity and location parameters—such as step count, phone use duration, and location-based data—were reported in 8 studies and captured through various digital interventions (see Table 4).
2. Behavioral patterns included parameters like user engagement, often assessed via response time to survey notifications. These were also reported in 8 studies.
3. Physiological data encompassed diverse indicators such as heart rate, circadian rhythms, and facial expressivity. These were observed in 8 studies and often overlapped conceptually with parameters categorized under “Sleep”, such as total sleep time, sleep onset, and nighttime heart rate. Sleep-related parameters were collected in 7 studies.
4. Sociability and self-reported assessments involved features inferred from communication behaviors, including the number and duration of phone calls, text message counts, and emoticon use. These were reported in 3 studies. Self-reported mood or symptom assessments, often gathered through in-app or EMA-style prompts, were present in nearly all included studies and frequently used alongside sensor data.

Figure 2. Common domains and parameters within domains used for digital phenotyping in depression monitoring.

19	No	No	No	No	No	No	—

[a]Not applicable.

Across the studies, the most robust prediction of depressive symptoms emerged from models that combined smartphone and wearable sensor data with self-reported assessments. Although there was considerable heterogeneity in the parameters used, ranging from location variability and facial expressivity to sleep duration and keystroke timing, some overlap was noted. For instance, nighttime heart rate could be classified under either physiological data or sleep, depending on the study context. In such cases, we categorized the parameter according to how it was used in the original study.

Elaboration of Key Findings

Physical Activity and Location

The majority of studies that gathered passive data continually also supplied data about patient's locations. Additionally, these studies tracked patients' physical activity via accelerometer sensor. Results regarding physical activity and location parameters were homogenous. One study described a negative association between variability of locations visited and symptoms of depression (r=−0.21) [13], showing that the more active the participant is (ie, the more locations visited), the lower the symptoms of depression appear to be, which can also infer social context, as more activity could also signify more social interactions. Similarly, another study described a negative correlation between higher MADRS scores and a lower average distance from home (r=−0.25) [38], supporting the argument that greater depression severity is associated with reduced physical activity.

Behavioral Patterns

Studies categorized in behavioral patterns predominantly focused on user engagement and behavior of the patient. One of the included studies revealed that lower user engagement results in higher depression scores [41]. Although, the engagement in this case was defined as the time it took the user to respond to survey notifications. The longer the time users took to respond, the less engaged they were and the more severe their depressive symptoms were shown to be. In line with this, another study noted a correlation between higher engagement and an increase in symptom improvement, described as a decrease in at least one of the depressive symptoms and/or a clinically significant improvement [41]. User engagement can be used to assess the severity of depressive symptoms, and it is also important for gathering data continually, especially for gathering relevant data such as location and accelerometer; hence, active user engagement was found to be essential [30] also in supporting the physical activity and location category.

Apart from engagement rates, other behavioral markers differed in relation to depressive symptoms as well. A prospective cohort study, included in this review, exploring factors associated with the onset and course of mental health conditions during adolescence reported a weak negative association between most of the 54 analyzed keystroke timing features and mental health

XSL•FO
RenderX

symptoms [32]. Machine learning models using keystroke features alone were shown to be unable to predict mental health symptoms, while speech patterns and other associated voice-related markers, such as words per minute, were found to be negatively correlated (r=−0.09) with PHQ-9 [27] indicating that higher depression scores are associated with decreased speech and expression, which potentially has value for the (5) sociability and self-reported assessments category as well.

Physiological Data

Common parameters in this category were difficult to compare, as they vary in nature. Multiple physiological markers were shown to correlate with the severity of depressive symptoms across studies. For instance, one study reported significant increases in multiple digital markers, especially in facial expressivity such as fear and anger [37]. These markers were shown to decrease often in frequency, correlating to changes in the MADRS scores. Concretely, head movement and amount of speech correlated with changes in the MADRS scores [37], while other physiological parameters were associated (r=0.70) with greater severity of depressive symptom, such as greater variation of nighttime heart rate [29]. Based on the daily number of steps, depressive symptoms were associated (r=0.62) with lower regularity of weekday circadian rhythms [29]. In fact, this particular study also reported overall a limited ability of digital biomarkers to detect depression in the whole sample [29]. However, stronger correlations (r=0.8 - 1.0) were described among pairs of variables in alpha power and gamma power spectra in electroencephalography with MADRS [38], indicating that some pairs of variables in electroencephalographic streams can be measured when depression scores are increasing as well, being potentially useful as a digital biomarker in the prediction of depression.

Sleep

Multiple studies reported sleep-related data, consisting of passively gathered data or sleep-related questionnaires such as the Pittsburgh Sleep Quality Index, the Sleep Hygiene Index, or the Epworth Sleepiness Scale. Results were comparatively homogenous. One study reported a significant positive association between the total sleep time and depression (r=0.15), also waking after the sleep onset and depression (r=0.20), as well as heart rate variability and anxiety (r=0.12) [13]. Similarly, another study described a negative correlation (r=−0.12) between reported sleep duration and PHQ-9 [27]. Eventually, a stronger correlation of sleep-onset time with PHQ-8 was found cross-sectionally, and a higher correlation (r=0.24) of wakefulness after sleep-onset with PHQ-8 was also observed longitudinally [39].

Sociability and Self-Reported Assessments

In this category, studies included parameters such as self-reported mood or parameters pertaining to social behavior and sociability (eg, phone calls, text messages, and other communication apps). Since this is a rather broad range, comparison is difficult. In accordance with earlier described results, one study reported a correlation of PHQ-9 with voice-related markers such as Voice Diary words per minute, Voice Diary sentiment, and Voice Diary duration (Mood Study App, Verily Life Sciences LLC). Markers such as call ringing until missed minutes (r=0.10) showed a correlation, and phone call count (r=−0.06) showed a negative correlation as well, as did emoticon count in text messages (r=−0.06), battery percentage (r=−0.7), and ambient audio level (r=0.10) [27].

Another study described a negative correlation of high MADRS scores with lower entropy of the usage time of communication apps and lower total count of communication app usage (r=−0.42), indicating a decreasing sociability as depression scores were increasing. A strong positive correlation (r=0.9) was noted between self-reported outcomes and total MADRS score [38]. User behavior was also analyzed in a different study that described a typical person using the mental health app 3 times a day for a total of 12 minutes over the course of 90 days. The most frequently used tools in this study app were the Thought Diary (MoodTools, Inquiry Health LLC) and the self-assessment tests [31]. Significant treatment and time interactions for the BDI, GAD-7, Recovery Assessment Scale (RAS), Rosenberg Self-Esteem Scale (RSES), and Sheehan Disability Scale (SDS) were described [42]. Another study reported that participation in Cognitive Behavior Immersion (CBI) sessions via app reduced symptoms of anxiety and depression in patients (r=−1.5) [20].

A large portion of findings within this category relies on behavior data and as such is closely related to the behavioral patterns category. However, apart from user behavior, social patterns such as social support are found to be influencing the severity of depressive symptoms and the prediction thereof. Web-based social support was found to predict the improvement of depressive symptoms [20] while social-rhythm-focused digital interventions were shown to benefit patients significantly. In fact, a more rapid rate of improvement according to the PHQ-8 was shown compared to nonpersonalized interventions [34]. Additionally, one study reported a greater decline in DASS-21 scores using personalized feedback derived from the experience sampling method (ESM) compared to using nonpersonalized feedback [43].

The majority of studies apply several categories with a range of parameters used. Commonly, at least 4 categories were used for monitoring, assessing, or tracking depression across digital tools of the studies included (see Table 4). The type of device used to deliver the support was not shown as a relevant factor in effectiveness, and high comparability between smartphone-based and nonsmartphone-based questionnaire scores was reported [42]. Nevertheless, it must be noted that categories are interdependent, and all studies used parameters existing across categories, focusing on multiple aspects.

Discussion

Principal Findings

By focusing on parameters rather than platforms or algorithms, this review responds directly to calls for greater comparability in digital phenotyping research. This scoping review identified five major categories of passively collected parameters commonly used in digital interventions for depression: (1) physical activity and location, (2) behavioral patterns, (3)

XSL•FO
RenderX

physiological data, (4) sleep, and (5) sociability and self-reported assessments. Most studies used a combination of smartphone-based and wearable sensors alongside self-reports. The strongest predictive value for depression outcomes was observed in studies that integrated multiple data sources, especially when combined with machine learning or subject-specific modeling approaches. Despite promising findings, the field remains methodologically fragmented and lacks standardization in both sensor use and clinical integration.

Five overall categories distinguished in this review contain relevant parameters for monitoring, assessing, and potentially predicting depression by combining self-assessment and digital phenotyping in digital interventions. The existing findings point that the categories of (1) physical activity and location, (2) behavioral patterns, (3) physiological data, (4) sleep, and (5) sociability and self-reported assessments appear across literature as interdependent categories, used across studies to monitor and predict depression by using various passively gathered data from parameters such as accelerometer sensor, location clusters, average distance from home, step count, phone usage, number of phone calls, heart rate, sleep time, and voice-related markers, among others. Moreover, additional parameters retrieved also include 11 frequently used clinical and self-assessment measurements such as PHQ-9, PHQ-2, CES-D, DASS-21, PHQ-8, MINI, MADRS, CSSRS, HDRS, BDI, and BDI-II (see Table 2).

This synthesis aligns with the World Health Organization guideline recommendations [21] for strengthening universal health coverage, where the role of digital health interventions is addressed particularly in line with the insufficient quality parameters that can assure optimal health care support [21]. While they emphasize the need for improved quality parameters in digital health, our findings indicate that such parameters are arguably not missing but are rather scattered across literature without comparative analysis. It might be argued that current work is one of the early efforts in the field to collect or summarize such parameters for digital health interventions overall in a more structured manner.

Previous research has often examined digital phenotyping and depression in isolation [8,19,46] or focused on either digital interventions [20,34,47-49] or productive models for symptom progression [13,33] without comprehensively linking all aspects. This review aims to contribute to bridging that gap by grouping relevant parameters into more standard categories.

Retrieved parameters in this review can be used as a comprehensive guideline in determining relevant aspects to be implemented into digital health interventions for depression to combine optimal sensors and self-assessment-based tools for monitoring and predicting depression outcomes. It can be argued that the interdependence of distinguished categories provides a more solid understanding for developing optimal digital health intervention in terms of monitoring and self-management support for depression. Combining these categories by implementing described parameters can support more beneficial outcomes for the end user of digital self-management tools for depression.

Synthesis of result sections of the included studies indicated that predicting depressive symptoms by combining clinical assessment and digital phenotyping is a promising approach for further improvement of digital interventions' reliability and efficiency for individuals living with depressive symptoms and major depressive disorder. In a study using a transfer learning approach, an improvement of 12% for one-day-ahead forecasting was noted [33]. Moreover, using the MADRS score as a baseline for depression severity, the highest correlation of prediction was reported with user self-reported assessment [33]. Among other such assessments were the PHQ-2 and a model consisting of the Bond and Lader lethargic-energetic visual analog scale and the Bond and Lader interested-bored visual analog scale plus the N-Back working memory task [38].

The scores obtained in a smartphone-based intervention correlated with the ratings of nonsmartphone-based HDRS. Concretely, the smartphone-based single-item self-rating of mood correlated negatively (r=−0.54) with the BDI sum of scores as well [42], indicating that the lower the perceived mood of the user was, the higher the depression score. Therefore, participant self-reported assessments can potentially be valuable in predicting depression severity when combined with digital phenotyping for higher accuracy and reliability. In line with that, the findings support prior work showing that self-reported assessments when combined with sensor data, can meaningfully predict depressive symptom severity [34,39,48].

Reflecting on the device delivering the intervention with a combined model of smartphone features, wearable features, and self-reported mood items is also noted in one of the retrieved studies' approaches [13].

However, this review also reveals substantial variability and methodological inconsistencies across studies. Among the retrieved studies there was a notable lack of standardization in contrast with the World Health Organization recommendations guidelines [21] addressing the quality parameters. Sample sizes, study and intervention duration, sampling frequencies, and types of intervention differed considerably. This was particularly evident when efforts for comparison during the charting procedures were made, mirroring concerns in literature about standardization and reproducibility [22,30,46]. Missing data was frequent, and most studies did not report a follow-up or provide justification for demographic admissions, therefore leading to the inclusion of studies assessing depression severity with validated measures with a notably limited amount of measurement scales used across studies. Taking into consideration the chronic nature of depression, it must be noted that short-term observations, less than 6 months, might also not be sufficient to successfully record meaningful changes in symptom trajectories or assess the sustained effectiveness of digital interventions for depression.

Across the included studies, it is important to distinguish between studies that primarily examined associations and those that validated predictive models based on digital data. Only a subset of studies (6/19) developed or evaluated models to predict depression status or symptom severity from digital signals, including work on behavioral and clinical modeling, cognitive task-based digital biomarkers, wearable-derived screening

XSL•FO
RenderX

models, and sensor-plus-EMA-based forecasting [13,27-29,33,39]. The remaining studies (13/19) were observational, feasibility, validation, or intervention trials. These studies primarily characterized associations between digital parameters and depressive symptoms, evaluated feasibility and engagement, validated self-report formats, or tested the clinical effects of digital interventions without undertaking formal predictive model validation [20,30-32,34-38,40-43]. This distinction underlines that much of the evidence base still addresses which digital features relate to depression, whereas a smaller subset of studies evaluates how well these features can support robust and generalizable prediction.

Considering the rapidly developing nature of digital interventions and digital phenotyping in the mental health field, multiple challenges in conducting this review were noted. While digital phenotyping has been increasingly used to monitor symptoms and to gather vast amounts of passive data, discovering studies that combine digital phenotyping with digitally delivered interventions proved challenging. Although many studies address digital tools or passive monitoring separately, only a small percentage integrate both, further showing the fragmentation within the field. Additionally, the narrow focus of this review on depression and depressive symptoms exclusively led to discarding similar studies focused on other mental illnesses, narrowing our evidence pool. Nevertheless, the assessment of studies in our review was rather challenging due to the enormous number of articles addressing either digital interventions and depression or digital phenotyping and depression but rarely combining all these areas of interest together. This observation further aligns with literature where similar limitations have been noted previously in an umbrella review of smartphone sensors for monitoring depression [10]. In this review, studies often focused on generalized categories rather than specific parameters, restricting reproducibility and cross-study comparison.

Strengths and Limitations

This review provides a structured synthesis of passively gathered parameters used in digital interventions for depression, supplementing existing reviews that focus exclusively on either digital phenotyping [8,46] or digital interventions [1,20,34,47,49]. By incorporating both, this review offers a clearer framework for understanding how sensor-derived data and self-reported assessments can be integrated in monitoring depression.

Although many high-quality systematic reviews and meta-analyses on digital phenotyping or digital interventions have been published, there is rather limited systematic literature synthesis known to the authors of this review that includes and combines all relevant terms such as “digital intervention,” “depression,” and “digital phenotyping.”

The review allows a structured overview of all relevant categories and parameters used in digital interventions that address depression with clinical measures and digital phenotyping methodology. An important strength of this review is the categorization of parameters. It allows a comparison across 5 interdependent categories, supporting efforts in the mental health field to determine and assure reliability in parameter use for future research and intervention designs, as well as clinical use, aligning also with World Health Organization recommendations [21].

Nonetheless, several limitations of this review need to be acknowledged. First, the review’s narrow scope, focusing exclusively on studies that used both validated depression assessments and digital phenotyping, may have excluded relevant work on related conditions or interventions that did not incorporate passive data collection. While this decision was made to enhance clarity and focus, it inevitably limited the breadth of the review, as noted in other recent scoping and mixed methods reviews as well [13,45]. Second, although passive data gathering enables the collection of large volumes of data over relatively short periods, a few studies reported that only a small proportion of the collected data was directly relevant to their hypotheses, raising concerns about potential publication bias or overinterpretation of limited findings.

Included studies mostly described individual interventions in detail, although many did not report the individual parameters measured but rather focused on larger terms, which we define in our study as categories. Even though general categories across studies were comparable, the lack of information on the exact data gathered through digital phenotyping leads to limited reproducibility of these studies as well as limited comparability with similar studies, thereby raising questions about the implications of such parameters for future studies. Missing data handling was an issue encountered in numerous studies, varying from a lack of explanation regarding the drop-out rates over user-related problems or confounders to basic demographic information. Similar methodological weaknesses have been described as well in prior meta-analyses of mental health data for depression [8,30,39].

Third, technical variability also limited comparison. Concretely, retrieved studies used different sensor types and different software, which could possibly influence data reliability. Technological difficulties were reported in some studies, though their influence on the reliability of data was rarely discussed. In line with that, few studies discussed the influence of signals being generated due to reasons outside of illness context as potential confounders (eg, the influence of weather conditions on the amount of time spent at home limiting both physical and social activity). Previous work has highlighted the need to better account for such nonclinical sources of signal variability [10,38].

Finally, this review confronts challenges comparable to those of many trials researching technology or digital devices, including limited transferability of results due to the nature of study populations. The users that participated in the included studies were for the most part younger people who are commonly more familiar and comfortable with the technologies used, apart from a few studies, and had only a few issues using the interventions as intended. However, this might not be the case with an older population, thus indicating that results may not necessarily be representative, an issue that has also been raised in other studies [31,35].

Although this review identifies promising directions for standardizing and optimizing digital interventions for depression, it also underlines the need for improved methodological

XSL•FO
RenderX

consistency, demographic inclusivity, and clearer reporting of sensor-derived parameters in the future.

Conclusion

This scoping review offers an innovative contribution by systematically identifying and synthesizing common digital parameters used across heterogeneous digital tools for monitoring and predicting depression. In contrast to existing reviews that predominantly focus on specific sensing modalities, predictive algorithms, or the effectiveness of digital interventions, this review adopts a parameter-centric perspective, enabling comparison across observational, predictive, and interventional study designs. By mapping convergent parameters irrespective of device type or analytic approach, the review provides a clearer understanding of which digital features are consistently associated with depressive symptoms and outcomes. This synthesis advances the field by supporting standardization efforts, guiding future predictive model development, and reducing fragmentation in digital mental health research. In real-world settings, these findings can inform the design of interoperable digital tools, facilitate integration into clinical monitoring workflows, and support personalized, data-driven depression management beyond controlled research environments.

Acknowledgments

We would like to sincerely thank the editor and anonymous reviewers for their constructive feedback and thoughtful suggestions which helped improve the clarity and quality of this manuscript. AI tools (ChatGPT, OpenAI) were used for editing/formatting assistance in the first revision round for refining the existing paragraphs and removing redundancy; authors critically reviewed and approved all content.

Funding

This research did not receive any specific grant from funding agencies in the public or commercial sectors.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

LB and UH conceptualized the study. LB, MP, and RA performed data extraction. LB and MP conducted the data analysis, while UH supervised the analysis process and contributed to clinical interpretation which then also supported the discussion. All authors contributed to the drafting of the manuscript and approved the final version.

Abstract

Background: Artificial intelligence (AI)–driven pose estimation (PE) offers a scalable and cost-effective solution to track exercises in mobile health apps. However, occlusion, influenced by camera angle and distance, can reduce detection accuracy and repetition counting precision. The influence of smartphone positioning on these performance metrics remains underexplored in controlled studies.

Objective: The study aimed to examine how smartphone camera angle (front, side, and diagonal) and distance (90 cm, 180 cm, 200 cm, and 360 cm) affect detection performance and repetition counting accuracy during push-ups and squats using AI-based PE.

Methods: In this cross-sectional, within-subject study, 44 healthy university students (9 [20.5%] female participants; mean age 20.3 y, SD 0.4 y; mean BMI 23.2, SD 0.6 kg/m²) were assigned to perform either squats or push-ups. Each participant completed their assigned exercise across 12 predefined smartphone camera configurations, yielding approximately 264 squat trials (n=22) and 264 push-up trials (n=22). Each trial consisted of an average of 5 repetitions, totaling approximately 1320 repetitions per exercise. PE performance was assessed using binary classification accuracy, detection rate, and mean absolute error (MAE) for repetition counting. Generalized linear mixed-effects models evaluated classification odds, linear mixed-effects models analyzed MAE, and Tukey-adjusted post hoc tests followed significant effects.

Results: The mean detection rate was 61.1% (SD 48.8%) for push-ups and 61.5% (SD 48.7%) for squats, with MAEs of 1.08 (SD 1.78) and 1.11 (SD 1.82) repetitions, respectively. Push-ups were most accurately detected from diagonal views at 90 to 180 cm (up to 85.7% detection; MAE=0.28) and least accurately from the front at 360 cm (20%; MAE=2.70). Squats performed best from a diagonal view at 200 cm (95.5%; MAE=0.05) and worst from the side at 90 cm (0%; MAE=5). Generalized linear mixed models showed that for push-ups, the front 90 cm and diagonal 360 cm views significantly reduced classification odds compared to the side 90 cm view (P=.03 and P=.04, respectively), whereas for squats, diagonal and front views significantly outperformed side views across all distances (P<.001). Post hoc tests confirmed that for push-ups, diagonal close or mid-range views had significantly lower MAEs than far front views, and for squats, diagonal and front views at 180 to 200 cm achieved the highest accuracy and lowest MAEs (P<.05).

Conclusions: AI-based PE effectiveness for exercise tracking is significantly affected by smartphone positioning. Diagonal and frontal views at mid-range distances (180 - 200 cm) provided the highest detection accuracy and counting precision. These findings offer actionable guidance for developers, clinicians, coaches, and users optimizing mobile health exercise monitoring.

KEYWORDS

computer vision; digital health; human pose estimation; human activity recognition; mobile health; mhealth; mobile apps; physical activity

Introduction

Physical inactivity is a major global public health concern, contributing to higher rates of chronic diseases, reduced quality of life, and increased health care costs [1-3]. While the health benefits of regular physical activity are well documented, ranging from improved cardiovascular fitness and muscle strength to enhanced mental well-being, participation levels remain insufficient worldwide [4]. Current estimates indicate that over 31% of adults and 81% of adolescents fail to meet the World Health Organization's recommended physical activity guidelines [5]. The consequences of physical inactivity are particularly severe for populations managing chronic or neurological conditions, for whom movement-based interventions can serve as both preventive and therapeutic measures [3,6,7].

In response to the demand for scalable and accessible physical activity tools, mobile health (mHealth) apps have emerged as a cost-effective means of promoting exercise participation [3]. A notable innovation in this field is pose estimation (PE), or markerless motion capture, which uses computer vision to detect joint positions from standard video footage without the need for specialized equipment [8]. Open-source PE models, such as OpenPose (Carnegie Mellon University), BlazePose (Google), and MoveNet (Google), facilitate real-time PE via smartphones or webcams. This enables the provision of remote, personalized feedback [9-13]. In biomedical contexts, PE can identify movement impairment patterns and support rehabilitation or neurological diagnoses [8]. It is also widely applied in fitness, telerehabilitation, occupational health, and sports to track joint angles, velocity, form, and repetitions [14-18]. Validation studies have demonstrated strong agreement with the gold standard motion capture [19-21], and recent studies integrating deep learning have reported repetition-counting accuracies above 90% [22-25].

Despite recent advances, most PE systems have only been evaluated in controlled laboratory environments. However, real-world mHealth apps occur in uncontrolled settings where factors such as handheld devices held at different distances and angles, and partial obstructions (eg, from pets, furniture, or body position) can significantly degrade performance [10,12,26]. These challenges are particularly pronounced for dynamic, whole-body movements such as squats and push-ups, where tracking accuracy can vary depending on body position and elevation. Although a few commercial solutions have begun to experiment with camera-based self-assessment (eg, Halo Movement [Amazon] [27] and Kaia Health GmbH [28]), there is still a lack of empirical studies on how smartphone positioning affects the reliability of PE in practical settings [10,14,27]. Improving accuracy in these contexts will likely require advances not only in 2D keypoint detection but also in our understanding of optimal camera placement and how to transform 2D keypoint data into accurate spatial representations.

This study systematically evaluates the impact of smartphone camera angle and distance on the performance of artificial intelligence (AI)–based PE when counting 2 foundational bodyweight exercises: squats and push-ups. These exercises are commonly used for fitness and rehabilitation tracking. They involve multijoint movements and present common occlusion challenges. Repetition counts are obtained from 2D PE across 12 camera configurations (3 angles × 4 distances) and benchmarked against expert-labeled ground truth. The aim is to examine how smartphone recording position, specifically camera angle and distance, affects detection performance and repetition counting accuracy, and to inform best practices for using mHealth systems in real-world environments. This work is part of the Blockchain.PT initiative (Project No. 51), which supports sustainable blockchain-based digital innovation in the health and sports sectors.

Methods

Study Design

This cross-sectional, within-subject study was designed to assess the influence of smartphone camera configurations, specifically angle and distance, on the detection of PE during squats and push-ups. These exercises were selected due to their complex multijoint biomechanics and typical self-occlusions (eg, torso obscuring limbs in push-ups).

Setting

All data were collected in a controlled laboratory environment at the School of Health and Human Development, University of Évora, Portugal, in May 2025. Environmental conditions, including lighting and temperature, were standardized across trials. Smartphone placement was controlled at predefined angles and distances to ensure reproducible video capture. The laboratory provided enough space for participants to safely perform push-ups and squats.

Participants

Participants were recruited from undergraduate courses at the University of Évora in Portugal through a targeted study announcement that specified the eligibility criteria, study procedures, and recommended attire for physical exercise during classes. Eligible volunteers were identified through convenience sampling with eligibility screening.

A total of 44 healthy university students participated and self-reported their status. Inclusion criteria were: (1) aged 18 years or over; (2) able to safely perform squats and push-ups; (3) not having used sedative or balance-impairing medications within the last 24 hours; and (4) absence of neurological or musculoskeletal conditions that could impair movement.

XSL•FO
RenderX

Ethical Considerations

The study protocol was reviewed and approved by the Ethics Committee of the University of Évora (GD/27378/2024), in accordance with institutional and international standards for human participant research. All procedures complied with the Declaration of Helsinki and the General Data Protection Regulation. Written informed consent was obtained from all participants prior to enrollment. Participants were informed about the study objectives, procedures, and potential risks and were explicitly advised of their right to withdraw at any time without penalty. To ensure privacy and confidentiality, all collected data were anonymized and coded to prevent participant identification. Data were securely stored on password-protected institutional servers accessible only to the research team. No monetary or material compensation was provided for participation in this study.

Exercise Protocol and Dataset

Participants were first briefed on the study protocol and completed a demographic questionnaire to record baseline characteristics. For the squat task, participants stood with feet shoulder-width apart and arms extended forward, performing repetitions by lowering their hips until their thighs were parallel to the floor. Male participants performed push-ups in a standard plank position, while female participants were allowed a modified knee-supported variation. All exercise procedures adhered to the 11th edition of the *American College of Sports Medicine* guidelines (2021) [29], which recommend these variations to accommodate differences in strength and fitness levels. To reduce fatigue-related performance decline and ensure high-quality movement data, participants were assigned to perform either squats or push-ups based on personal preference. Of the 44 participants, 22 (16 male participants and 6 female participants) completed the squat protocol, and 22 (19 male participants and 3 female participants) completed the push-up protocol. Each participant performed their assigned exercise across all 12 predefined camera configurations, yielding 264 squat trials (22×12) and 264 push-up trials (22×12). Each trial consisted of a continuous movement sequence, averaging approximately 5 repetitions per video [16], totaling approximately 1320 repetitions per exercise type (264 trials × ~5 reps).

Experimental Setup

To capture a representative sample of commonly used consumer devices, exercise sessions were recorded using three smartphone models, iPhone 11 (Apple Inc.), iPhone 13 (Apple Inc.), and Samsung Galaxy A52 (Samsung Electronics), each capturing video at 1080 p resolution and 30 frames per second. Smartphones were positioned horizontally on the floor at 3 fixed angles relative to the participant's body: frontal (0°), diagonal (45°), and lateral (90°). Recordings were conducted at 4 distances, including 180 cm based on prior literature [30], and 3 additional distances (90 cm, 200 cm, and 360 cm) defined by the research team to test a wider range of realistic recording conditions. This configuration resulted in 12 distinct camera setups (3 angles × 4 distances). All smartphone positions were marked and standardized to ensure consistency across trials.

This experimental setup is contextualized within existing research by Table 1, which summarizes previous studies on push-up and squat detection, detailing camera perspectives, distances, PE methods, and reported performance metrics. The comparison shows that most prior studies rely on limited viewpoints and fixed distances, restricting generalizability. In contrast, our multiangle, multidistance dataset addresses these constraints, providing a more diverse and representative resource for evaluating PE performance.

Pose Estimation and Processing

Video data were processed using a multistage PE and repetition detection pipeline designed for real-world deployment on the Dotmoovs mobile platform [37]. The pipeline was optimized for low-latency, on-device inference while maintaining sufficient accuracy for exercise recognition.

Model Selection

A lightweight 2D PE model was prioritized to ensure real-time performance on consumer smartphones and without requiring external sensors. Among candidate architectures (eg, PoseNet [Google], BlazePose, and MoveNet), MoveNet was selected due to its computational efficiency, suitability for edge inference, and enhanced generalization to fitness-related movements. MoveNet was trained on the COCO (Common Objects in Context) dataset (Microsoft) and Google's internal Active dataset, which includes annotated yoga, fitness, and dance poses exhibiting substantial motion variability [38-40]. For cloud-based processing, EvoPose2D (Huawei Technologies Co, Ltd) and ViTPose (Microsoft Research Asia) were implemented to achieve higher precision at the cost of increased computational load. This hybrid configuration balances latency, accuracy, and hardware constraints, supporting both on-device responsiveness and scalable cloud inference [39]. The models were trained on approximately 1 million samples, reserving 10,000 samples each for validation and testing, ensuring robustness and generalizability across diverse movement types.

Training Datasets and Domain Adaptation

To improve robustness for fitness-specific postures, the training pipeline incorporated multiple publicly available datasets: SMART (Sports Motion and Recognition Tasks) [41], LSP (Leeds Sports Pose) Extended [42], Penn Action [43], and MPII Human Pose [44]. Despite these datasets, complex movements, particularly floor-based exercises (eg, push-ups), remained challenging for accurate PE. This motivated the creation of DotPose, a custom internal dataset designed to complement existing datasets and improve the detection of occluded limbs and challenging postures. The combination of DotPose with public datasets further mitigates potential biases related to body types, cultural differences, exercise contexts, and environmental scenarios, thereby enhancing generalizability across diverse users and real-world conditions.

Pipeline Implementation

The PE outputs (17 keypoints per frame) were processed through a proprietary deep learning module performing two primary tasks:

1. State classification: A lightweight neural network classifies each frame into discrete movement states (eg, squat-down, squat-up, or other).
2. Repetition counting: A Markov-chain-based algorithm tracks temporal transitions between states, triggering a repetition event when a predefined sequence (eg, up-down-up) is detected.

This architecture ensures temporal stability and robustness against intermittent keypoint noise. The pipeline was benchmarked for real-time inference, with MoveNet demonstrating subsecond latency, suitable for interactive mobile feedback. Finally, all pose outputs were exported in comma-separated values format to enable statistical analysis of accuracy and classification metrics across varying camera angles and distances.

Manual Annotation

All video samples were independently annotated by 2 trained raters (an exercise physiologist and a physical therapist), who followed a predefined schema based on standardized exercise movement criteria. Each annotator labeled the exercise type and manually counted the number of valid repetitions per trial. No discrepancies were observed between raters. These annotations were then used to evaluate the accuracy of detection and repetition counting.

Statistical Analysis

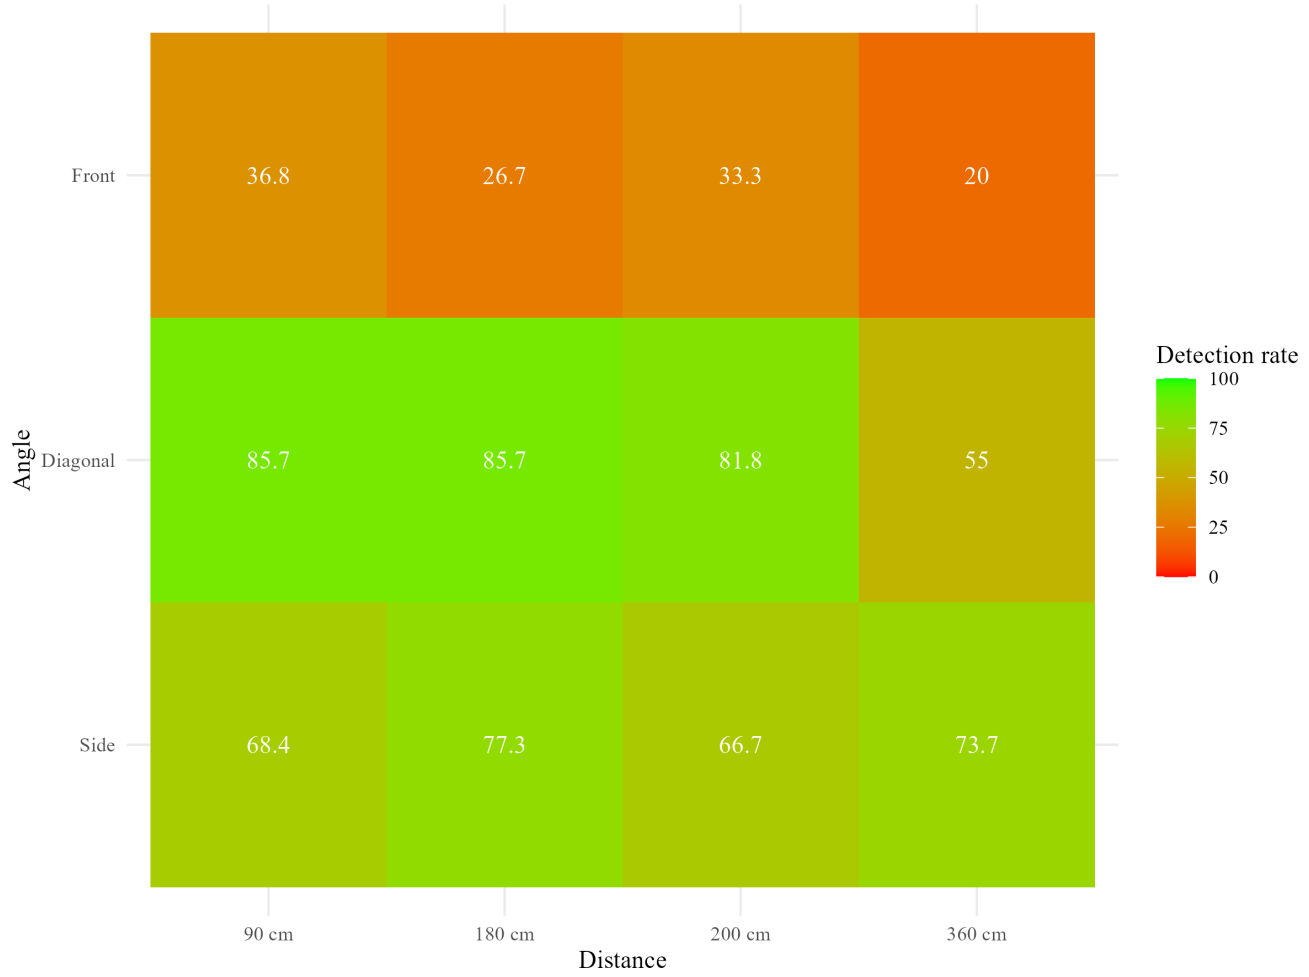
All analyses were conducted in RStudio (version 4.5.0; R Foundation for Statistical Computing) using established packages including lme4, lmerTest, emmeans, and performance. Performance metrics were reported in alignment with prior benchmark studies in human activity recognition and AI-based motion analysis [26,45]. The primary outcome was a binary accuracy indicator, coded as 1 when the system's predicted repetition count exactly matched the ground truth, and as 0 otherwise. This was modeled using generalized linear mixed-effects models (GLMMs) with a logit link. The secondary outcome was the mean absolute error (MAE), defined as the absolute difference between predicted and ground-truth repetition counts per video, modeled using linear mixed effects models (LMMs) with a Gaussian distribution. For descriptive reporting purposes, we also calculated a detection rate for each video, defined as (prediction or ground truth) x100, representing the percentage of repetitions counted correctly. Both models included camera angle and distance as fixed effects, with participant ID modeled as a random intercept to account for intraindividual variability and repeated measures. When the fixed effects were statistically significant ($P<.05$), Tukey-adjusted post hoc contrasts were conducted to compare condition pairs. Odds ratios (ORs) were computed by exponentiating the log odds from the GLMM to facilitate interpretation.

Results

Participant Characteristics

Our dataset comprised 44 healthy university students from the University of Évora, Portugal, including 9 (20.5%) females and 35 (79.5%) males. The participants had a mean age of 20.31 (SD 0.40) years, a mean height of 1.74 (SD 0.09) meters, and a mean body mass of 70 kg (SD 14.72), resulting in a mean BMI of 23.16 kg/m² (SD 0.61).

Based on previous studies assessing AI-based PE for push-up and squat detection [24], we assumed a medium-to-large expected effect size (Cohen d=0.65) for power estimation. A post hoc analysis conducted in G*Power 3.1 (Heinrich Heine University Düsseldorf) indicated that the current sample size (n=44) provides approximately 0.74 statistical power to detect this effect at a 2-tailed significance level of α=.05, suggesting



XSL•FO
RenderX

adequate sensitivity for detecting meaningful differences in PE performance across camera conditions.

Push-Up Performance

Table 2 shows detection rates and MAEs for push-ups across camera angles and distances. Overall, the mean detection rate was 61.1% (SD 48.8%), with an average MAE of 1.08 (SD 1.78) repetitions. Detection rates peaked for diagonal views at 90 cm and 180 cm (both 85.7%, SD 35.9%), as illustrated in Figure 1. The corresponding MAEs at these distances were low, at 0.29 (SD 0.90) repetitions. In contrast, the front view at 360 cm showed the lowest detection rate of 20% (SD 41.0%) and the highest MAE of 2.70 repetitions (SD 2.05).

Figure 1. Detection rate of push-ups across distances and angles.

Table . Detection rate and MAE[a] for push-ups across camera angles and distances.

Camera angle	Distance (cm)	Detection rate (%), mean (SD)	MAE, mean (SD)
Side	90	68.4 (47.8)	0.842 (1.537)
Side	180	77.3 (42.9)	0.409 (0.796)
Side	200	66.7 (48.3)	1.095 (1.972)
Side	360	73.7 (45.2)	0.789 (1.653)
Diagonal	90	85.7 (35.9)	0.286 (0.902)
Diagonal	180	85.7 (35.9)	0.286 (0.902)
Diagonal	200	81.8 (39.5)	0.227 (0.528)
Diagonal	360	55.0 (51)	1.500 (2.482)
Front	90	36.8 (49.6)	1.684 (1.974)
Front	180	26.7 (45.8)	2.067 (2.017)
Front	200	33.3 (48.8)	1.733 (1.981)
Front	360	20 (41)	2.700 (2.055)

[a]MAE: mean absolute error.

The GLMM (Table S1 in Multimedia Appendix 1) revealed a significant main effect of camera angle on accuracy. Specifically, front views had significantly lower odds of detection (OR=0.17, *P*=.03). However, no significant effects of distance alone were found. Conversely, a statistically significant interaction was found between the diagonal view and the 360 cm distance, which reduced the ability to correctly identify push-ups (*P*=.04).

Post hoc pairwise contrasts were performed to examine differences between the specific camera angles and distances (Table S2 in Multimedia Appendix 1). These contrasts confirmed that diagonal camera views at 90 cm significantly outperformed frontal views at all distances, including 90 cm (estimate=3.41, *P*=.019), 180 cm (estimate=3.67, *P*=.02), 200 cm (estimate=3.52, *P*=.02), and 360 cm (estimate=4.40, *P*<.001). There were also notable differences in the multiple mid-range diagonal and frontal configurations: the diagonal 180 cm view outperformed the frontal 180 cm view (estimate=3.64, *P*=.02), 200 cm (estimate=3.50, *P*=.03), as well as 360 cm (estimate=4.35, *P*=.002).

Likewise, the diagonal 200 cm view surpassed the frontal 360 cm view (estimate=3.96, *P*=.003). Additionally, the side views at 180 cm and 360 cm were significantly better than the frontal 360 cm view (estimate=3.586, *P*=.008, and estimate=3.174, *P*=.03, respectively). These results demonstrate that diagonal and mid-range frontal camera placements substantially increase push-up detection accuracy compared to frontal or side views at extreme distances.

Analyses of push-up repetition MAE using LMM were conducted to evaluate the error comparisons in the respective configurations. Although the main effects of angle and distance were not individually significant beyond the intercept (Table S3 in Multimedia Appendix 1), Tukey's post hoc tests (Table S4 in Multimedia Appendix 1) revealed meaningful differences between specific camera setups. Diagonal angles at mid-range distances consistently reduced counting errors compared with frontal and side angles at extreme distances. Diagonal views at 90 cm and 180 cm, for example, significantly outperformed frontal views at 180 cm and 360 cm (estimates=−1.686 to −2.395, *P*=.04). Diagonal views at 200 cm were also superior to frontal views at 360 cm (estimate=−2.428, *P*<.001). Side views at extreme distances exhibited higher MAE than frontal views at 360 cm (estimate=−1.800, *P*<.01). Overall, these results suggest that diagonal positioning at mid-range distances (approximately 180R - 200 cm) minimizes counting errors in push-ups.

Squat Performance

Table 3 shows detection rates and MAEs for squats across camera angles and distances. Overall, the mean detection rate was 61.5% (SD 48.7%), with an average MAE of 1.11 (SD 1.82) repetitions. Detection rates peaked for the diagonal view at 200 cm (95.5%, SD 21.3%), as illustrated in Figure 2. The corresponding MAE at this distance was minimal, at 0.05 (SD 0.21) repetitions. In contrast, the side view at 90 cm showed the lowest detection rate of 0% (SD 0%) as well as the highest MAE of 5 (SD 0) repetitions.

Diagonal	180	90.9 (29.4)	0.091 (0.294)
Diagonal	200	95.5 (21.3)	0.045 (0.213)
Diagonal	360	90.9 (29.4)	0.091 (0.294)
Front	90	86.4 (35.1)	0.318 (0.945)
Front	180	81 (40.2)	0.571 (1.248)
Front	200	90 (30.8)	0.4 (1.273)
Front	360	70 (47)	1.1 (1.889)

[a]MAE: mean absolute error.

Analyzing the binary accuracy through the GLMM (Table S5 in Multimedia Appendix 1) demonstrated that the diagonal and frontal angles significantly outperformed the side angle at 90 cm (OR=20.43, *P*<.001, and OR=23.01, *P*<.001, respectively). Detection also significantly improved at mid-range distances of 180 cm (OR=4.36, *P*=.002), 200 cm (OR=7.62, *P*<.001), and 360 cm (OR=3.054, *P*=.01) compared to 90 cm. Post hoc pairwise comparisons (Table S6 in Multimedia Appendix 1) revealed that the diagonal view at 180 cm significantly outperformed the front view at 90 cm (estimate=2.810, *P*=.02) and the front view at 180 cm (estimate=3.058, *P*=.009). However, it underperformed compared to the front view at 200

XSL•FO
RenderX

cm (estimate=−3.271, *P*=.01) and the front view at 360 cm (estimate=−4.016, *P*=.02). Side views at 180 cm and 360 cm outperformed the front view at 360 cm in correctly detecting push-ups (estimates=2.907 to 3.239, both *P*=.04). The diagonal view at 200 cm had significantly better detection accuracy than the front view at 360 cm (estimate=3.174, *P*=.03). These findings suggest that diagonal mid-range placements generally perform well, but that frontal views at longer distances (200 and 360 cm) can sometimes outperform the diagonal view at 180 cm for squat detection.

For squats, LMM analysis of MAE (Table S7 in Multimedia Appendix 1) revealed significantly lower errors for diagonal and frontal angles compared with the side (estimates were −3.682 and −4.682, respectively; both *P*<.001). All tested distances (180 cm, 200 cm, and 360 cm) were superior to the 90 cm reference (estimates ranged from −4.364 to −1.910; *P* values<.001). Several significant interactions were observed. For instance, combining a diagonal angle with 180 cm or 200 cm decreased MAE by 3.06 and 3.09 repetitions, respectively (both *P*<.001), which moderated the improvements to the main effects expected from angle and distance independently. The front × 180 cm interaction (estimate=4.547, *P*<.001) and the front × 200 cm interaction (estimate=4.460, *P*<.001) exhibited similar patterns, indicating smaller improvements than the sum of the main effects predicted. In the model, only the diagonal × 360 cm interaction was nonsignificant (*P*=.16). Several significant post hoc pairwise comparisons were identified (Table S8 in Multimedia Appendix 1). These confirmed that diagonal and frontal mid-range placements consistently minimized error. Diagonal at 200 cm produced the largest reduction (estimate=−4.96 repetitions, *P*<.001), similar to diagonal at 180 cm (estimate=−4.91 repetitions, *P*<.001). Most configurations substantially reduced MAE compared to the 90 cm side, but the magnitude of improvement depended on the specific combination of angle and distance. This highlights notable interaction effects.

Discussion

Main Findings

This study demonstrates that smartphone camera angle and distance critically affect the accuracy of PE models for detecting and counting push-ups and squats. Consistent with our results, camera placements at intermediate distances (180 - 200 cm) combined with oblique (diagonal) or frontal views generally yielded the highest detection rates and lowest counting errors. In contrast, very close-range setups (90 cm) and long-distance frontal views (360 cm) often showed reduced performance. For push-ups, diagonal views between 90 and 200 cm outperformed frontal angles, with the diagonal view at 200 cm position achieving the lowest MAE. For squats, diagonal and frontal views at 180 to 200 cm significantly outperformed side views, with diagonal 180 cm, diagonal 200 cm, and front 200 cm producing the smallest MAEs and the largest error reductions in post hoc tests. Although front 360 cm occasionally approached the accuracy of diagonal 180 cm, most mid-range configurations substantially outperformed both close-range and long-distance side views. These findings provide direct evidence that mid-range diagonal and frontal camera configurations optimize PE performance, informing best practices for smartphone-based exercise monitoring.

Comparison to Prior Work

Unlike prior lab-based, multicamera studies [11,31], our study provides practical, configuration-specific guidance for monocular smartphone setups. This approach enhances ecological validity by closely mimicking typical home or gym environments where single-camera devices are commonly used. While [17] demonstrated that full-body visibility at 300 cm supports accurate gait tracking, we show that diagonal views at 180 to 200 cm consistently optimize visibility and accuracy for dynamic strength exercises. Views at 360 cm, however, yield variable and often low detection rates (push-ups: 20% - 73.7%; squats: 23% - 90.9%), depending on the angle [46], evaluated smartphone-based distance estimation between 100 and 300 cm, the trade-offs between spatial accuracy, and usability. Our findings confirm that mid-range diagonal placements are optimal for PE performance, likely due to differences in exercise posture (horizontal for push-ups vs upright for squats).

Prior studies have evidenced smartphone apps using TensorFlow Lite and COCO-trained models for exercise counting [10,47], but have not comprehensively examined spatial configuration effects. Our results address this gap, complementing [48] who emphasized viewpoint in PE data acquisition [9], advocating for accessible PE tools beyond labs, and [12] who discussed challenges of motion tracking in naturalistic settings. By offering concrete camera setup recommendations, this work contributes actionable insights for mHealth, home fitness, telerehabilitation, sports performance, and clinical decision-making contexts.

Practical Implications for mHealth

Positioning the smartphone camera diagonally (~45°) at 180 to 200 cm significantly enhances PE accuracy without additional hardware. Mobile apps can integrate augmented reality or setup guides to assist users in achieving optimal device placement. Accurate repetition counting supports load monitoring, fatigue tracking, and muscular endurance assessment in unsupervised environments [29,49,50]. Combining spatial optimization with adaptive feedback and personalized experiences may further improve tracking reliability and user engagement, consistent with evidence from behavior change and human-computer interaction research [51,52]. This integrated approach presents a promising path for scalable, user-friendly mHealth exercise platforms.

Limitations

This study has several limitations. First, PE performance was evaluated using manual annotations rather than a gold-standard motion capture system, which may introduce variability. Second, the sample comprised healthy young adults in a controlled laboratory environment, limiting generalizability to clinical populations, older adults, or real-world contexts with variable lighting and backgrounds. Third, while only 1 PE pipeline was tested, integrating multiple public datasets and the custom DotPose dataset helped mitigate biases related to scene composition, body type, exercise variety, and environmental

XSL•FO
RenderX

scenarios. Furthermore, comparisons with other open-source PE models (eg, OpenPose, HRNet [Microsoft Research Asia], and BlazePose) are limited by variations in datasets, computational demands, and architectural design [12,35,53]. Finally, lightweight 2D models, such as MoveNet, enable near-real-time, on-device inference. These models balance speed, portability, and user engagement with the fine-grained accuracy achievable by heavier, cloud-reliant models [13]. This hybrid mobile-cloud configuration supports the robust evaluation of push-ups and squats across multiple camera setups. Nevertheless, findings may not generalize to other PE architectures, populations, or unstructured environments.

Future Directions

Future work should explore multimodal pipelines, diverse participant groups, and variable environmental conditions (eg, low-light and high-contrast conditions) to enhance robustness, applicability, and real-world relevance of mobile PE systems. While repetition counting is a fundamental first step, future mHealth systems should also evaluate movement quality. This should encompass compensatory strategies and fatigue-related adaptations [54-56]. Emerging real-time PE technologies that optimize sensor or camera placement, combined with adaptive feedback responsive to user performance, offer opportunities to enhance movement accuracy and user experience in unsupervised settings [28,48,57,58]. Longitudinal studies are needed to assess the integration of spatial setup guidance, personalization, and real-time feedback for improved usability, engagement, and long-term clinical or fitness outcomes.

Conclusions

Camera angle and distance significantly affect the accuracy of PE systems for exercise detection. For optimal performance, smartphone cameras should be positioned at mid-range distances (180 - 200 cm) with diagonal or frontal views. For push-ups, diagonal views are preferred, while for squats, both diagonal and frontal views perform well. Conversely, close-range setups (90 cm) and long-distance frontal views (360 cm) substantially reduce detection and counting accuracy. These findings provide actionable guidance for developing scalable, accurate, and user-friendly mHealth exercise tracking platforms.

Acknowledgments

The authors would like to thank the students who participated in this study for their time and commitment. They would also like to acknowledge the University of Évora for its support in facilitating the research. During the preparation of the manuscript, ChatGPT was used to suggest grammatical edits. The authors reviewed and edited all content and took full responsibility for the final version.

Funding

This work was financially supported by Project Blockchain.PT—Decentralize Portugal with Blockchain Agenda (Project 51), WP4 Sports, Leisure, and Culture, Call number 02/C05-i01.01/2022, funded by the Portuguese Recovery and Resilience Program, the Portuguese Republic, and the European Union under the framework of the Next Generation European Union Program. The funders had no involvement in the study design, data collection, analysis, interpretation of results, or the writing of the manuscript.

Data Availability

The study leveraged established benchmark datasets for human pose estimation, including COCO (Common Objects in Context) [38], SMART (Sports Motion and Recognition Tasks) [41], LSP (Leeds Sports Pose) Extended [42], Penn Action [43], and MPII Human Pose [44]. Additionally, the data collected from the 44 participants are available from the corresponding author upon reasonable request.

Abstract

Background: Childhood obesity and unhealthy dietary habits remain major public health concerns and are influenced by the surrounding food environment. Food marketing, particularly for ultraprocessed foods (UPFs), shapes children's food preferences and consumption. However, food environments are complex and constantly changing, making them difficult to map and monitor. Developing approaches that capture these dynamics is essential to understand and address children's exposure to unhealthy food marketing.

Objective: This study aimed to pilot-test a novel tool consisting of a smartphone app and dashboard designed to identify areas where children are exposed to outdoor food advertising. Additionally, the study assessed the prevalence of advertisements for UPFs, health-promoting foods, and offers in the identified areas and explored differences in exposure by city size and socioeconomic status (SES).

Methods: A cross-sectional study was performed in 2 Swedish counties. Initially, 46 children from 4 schools in areas with varying SES used a smartphone app to take pictures of food advertisements that they encountered in their everyday lives. The app also recorded the GPS locations of where the pictures were taken. Pictures with associated GPS data were automatically uploaded and visualized in a web-based dashboard, allowing for identification of areas where children see many food advertisements, so-called "hotspot areas." The identified hotspot areas were subsequently visited by 2 researchers (SS and PF), who systematically photographed all food advertisements in the areas. All pictures taken by the researchers were later analyzed based on their content of UPFs, health-promoting foods such as fruits, berries, vegetables, and seafood (FBVS), and price promotions.

Results: Based on 1308 pictures of outdoor food advertisements taken by children using the app, 34 hotspot areas were identified through the dashboard. In these areas, researchers collected 2955 pictures of outdoor food advertisements during the mapping activity. Overall, 77.5% (2291/2955) of advertisements promoted UPFs, with no significant difference between the large and small cities. In Stockholm, a higher proportion of UPFs appeared in the high-SES area compared to the low-SES area, though the proportion was high in both areas. FBVS featured in 20.8% (616/2955) of advertisements, slightly more often in Stockholm and in the high-SES area. Price promotions appeared in 23.6% (697/2955) of advertisements, mainly featured UPFs (518/697, 74.3%) and less often FBVS (142/697, 20.4%). Price promotions for UPFs were somewhat more frequent in Stockholm, and FBVS promotions were more common in the high-SES area.

Conclusions: Using a novel, child-centered, mobile health tool combining a smartphone app and dashboard, this study identified local food advertising hotspots. Most advertisements in the hotspots promoted UPFs, while a few featured FBVS, a pattern also reflected in price promotions. These trends were consistent across areas, highlighting a food marketing landscape misaligned with dietary guidelines and the need for policy action.

Introduction

The prevalence of childhood obesity has increased dramatically in Sweden over the past few decades, following global trends [1,2]. This is concerning since childhood obesity is associated with an increased risk of several chronic diseases, including type 2 diabetes and cardiovascular disease, as well as various psychological problems, including low self-esteem and depression [3,4]. Moreover, childhood obesity increases the risk of obesity and developing chronic diseases in adulthood [5,6].

Poor dietary habits are a major modifiable risk factor for obesity. In recent years, increasing attention has been given to the role of the food environment in shaping poor dietary habits [7]. In parallel with the increase in obesity, the food environment has undergone rapid and widespread changes, resulting in increased access to cheap foods that are low in nutrients and high in calories, such as ultraprocessed foods (UPFs) [8]. High availability and consumption of UPFs have been associated with increased risk of obesity in both children [9] and adults [10,11], as well as an increased risk of all-cause mortality [12,13]. Conversely, the consumption of foods such as fruits, vegetables, whole grains, fish, and seafood is associated with protective effects against obesity and noncommunicable diseases [14]. This contrast points to the value of mapping food environments to inform strategies that promote healthier diets.

Food marketing represents a key element of the food environment, influencing food choices and consumption patterns. A growing number of studies show that the physical food marketing landscape is dominated by advertisements for foods associated with negative health outcomes such as UPFs [15]. A review assessing studies from 21 countries found that on average, 63% of food advertisements promoted unhealthy foods [15]. However, different studies use different terminology, including UPFs, “discretionary foods,” “noncore foods,” and “junk food,” to describe more or less the same type of unhealthy food items [15]. Studies investigating food advertisements around schools have found that the vast majority (~60%-90%) of food advertisements market unhealthy foods [16-23].

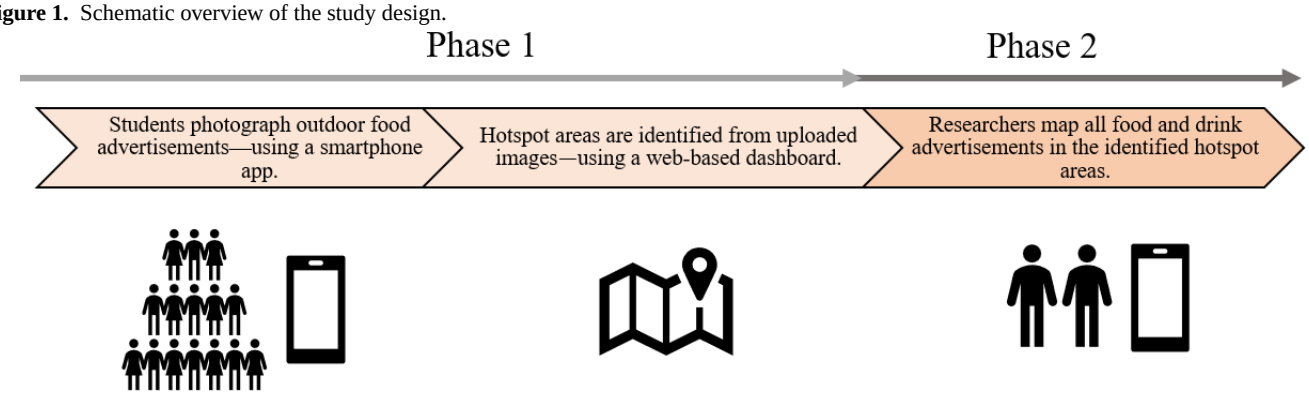
Food environments dominated by UPF marketing pose a health risk, as food marketing has been linked to increased intake, altered preferences, and purchase requests in children [24]. Experimental studies show that children exposed to food advertisements, on television or in advergames, consume more calories than those exposed to nonfood advertisements [25-27]. These effects are greater in children with overweight or obesity [25], and exposure increases the likelihood of choosing advertised products [27]. The impact of promoting healthier foods remains uncertain, as most studied products are of low nutritional value [27].

Beyond general exposure, the distribution of food advertising may also vary by socioeconomic status (SES). Our previous study conducted in 2 Stockholm neighborhoods, 1 with low SES with higher rates of childhood obesity and 1 with high SES with lower rates of childhood obesity, found that 65% of food advertisements promoted UPFs, with a higher proportion in the low-SES area (73%) compared to the high-SES area (59%) [28]. Studies from other countries have shown mixed results in regard to SES differences [15].

Mapping and measuring food environments, including exposure to food advertising, present several challenges due to their constant change and complexity [29]. This underscores the need for methods that enable continuous or repeated assessments without requiring extensive resources. To fully understand the scope and public health implications of food environments, it is also essential to use diverse measurement approaches that address multiple dimensions of the food environment [29]. Mobile health (mHealth) technologies, such as smartphone apps, offer a promising solution by facilitating real-time data collection directly from participants. These tools can capture locational, behavioral, and environmental information, allowing researchers to identify patterns of exposure and behavior in different groups or individuals and over time. Integrating mHealth approaches can therefore enhance both the efficiency and depth of environmental assessment, providing valuable insights into how food marketing and other environmental factors influence health outcomes and inform policy design.

While previous studies have investigated the outdoor food advertising landscape around schools and other locations frequently visited by children, the mapped areas have typically been defined by researchers [16-23,28,30]. In contrast, this study adopts a child-centered approach to investigate children’s exposure to outdoor food advertising.

Given this context, the objectives of this study were (1) to pilot-test a novel tool, including a smartphone app and a dashboard, designed to identify areas where children are exposed to outdoor food advertising; (2) to assess the proportion of UPFs, health-promoting foods (such as fruits and vegetables), and price promotions for food and beverages within the identified areas; and (3) to examine potential differences in exposure by city size and SES.



Methods

Study Design

A cross-sectional study was performed from April to June 2022. The study took place in 2 Swedish counties: Stockholm County (Stockholm) with approximately 2.5 million inhabitants (in 2024) [31] and Gävleborg County (Gävleborg), located approximately 200 km north of Stockholm, with approximately 0.3 million inhabitants (in 2024) [31]. In phase 1 of the study, a tool consisting of a mobile app and a dashboard was used to identify areas where children are exposed to many food advertisements (hotspot areas). In phase 2, researchers systematically mapped all food advertisements within the identified hotspot areas to quantify the types of food being advertised (see Figure 1 for a schematic presentation of the study design).

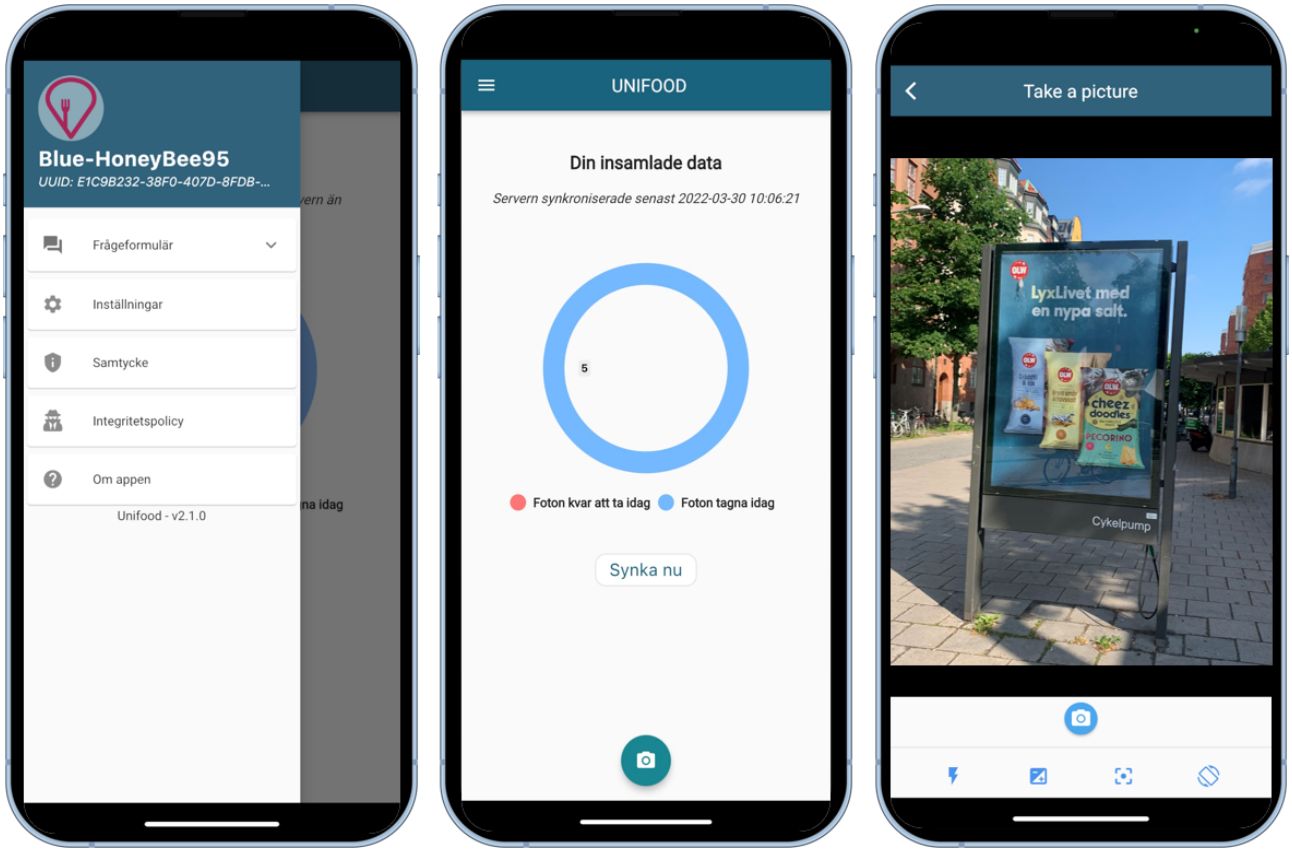
XSL•FO
RenderX

Figure 1. Schematic overview of the study design.

Participants and Recruitment

Children were recruited from secondary schools in Stockholm and Gävleborg. The aim was to include schools from areas with different SES in both a larger and a smaller city. Recruitment began by contacting schools in areas with varying SES levels via email and inviting them to participate. In total, 8 schools initially expressed interest, and online meetings were held to provide teachers with detailed information about the study. Ultimately, 4 schools were included based on expressed interest and scheduling availability during the study period.

In Stockholm, the capital of Sweden, areas with high and low SES were clearly distinguishable. In contrast, in Gävleborg, which is a smaller county, areas were more mixed. Consequently, clear SES differences were only present between the schools in Stockholm. The SES of the included areas was determined using the Segregation Barometer, a tool developed by the Swedish National Board of Housing, Building and Planning that incorporates statistics on education, income, health, and related factors [32].



The four participating schools were located (1) in Östermalm, an urban area in central Stockholm with high SES (~83,000 inhabitants in 2021); (2) in Södertälje, an urban area in the outskirts of Stockholm with low SES (~76,000 inhabitants in 2020); (3) in central Gävle, an urban area with mixed SES; and (4) in Bomhus, an area with mixed SES in the outskirts of Gävle (~79,000 inhabitants in Gävle in 2020). Each of the 4 participating schools selected 1 or 2 school classes with students aged 13 to 14 years for participation in the study. Given the exploratory nature of the study, the sample size was determined based on feasibility and participant accessibility, rather than formal statistical calculations.

Data Collection Tools: Mobile App and Dashboard

The data collection tools for this study consisted of a custom-developed smartphone app and a purpose-built web-based dashboard. These tools were designed primarily to facilitate the identification of hotspot areas based on participant reports. The app's key feature was a camera function that allowed users to take pictures of outdoor food advertisements (Figure 2). Along with the picture itself, the app recorded the GPS location of where it was taken. When the smartphone was connected to the internet (via Wi-Fi or mobile data), the pictures with associated GPS data were automatically uploaded to a secure server and visualized in the dashboard. The app also included a function that assigned users random usernames upon registration in the app, a questionnaire in which users could answer questions about their gender, age, height, and weight (Figure 2), and visual feedback on each user's daily photo contributions (Figure 2).

XSL•FO
RenderX

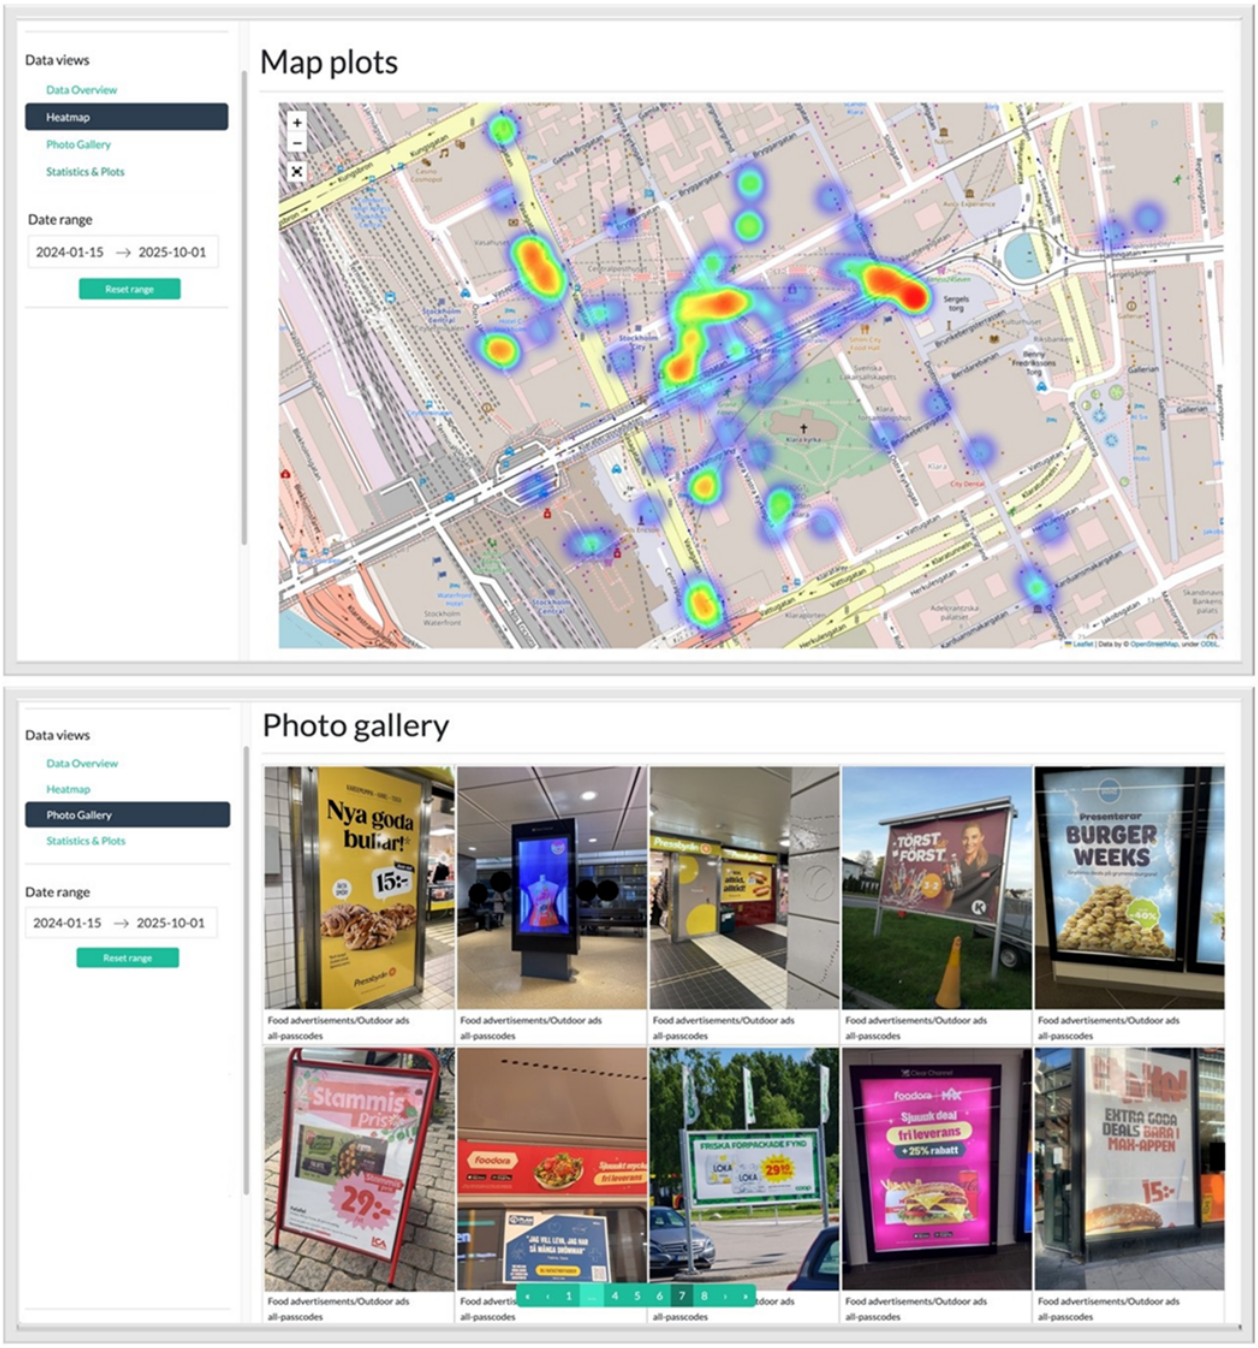


Figure 2. The mobile app used by the participants to take pictures of food advertisements. Left: the menu with information about the username and access to questionnaires and settings. Middle: the main screen of the smartphone app illustrating the daily picture contribution in blue. Right: the camera function.

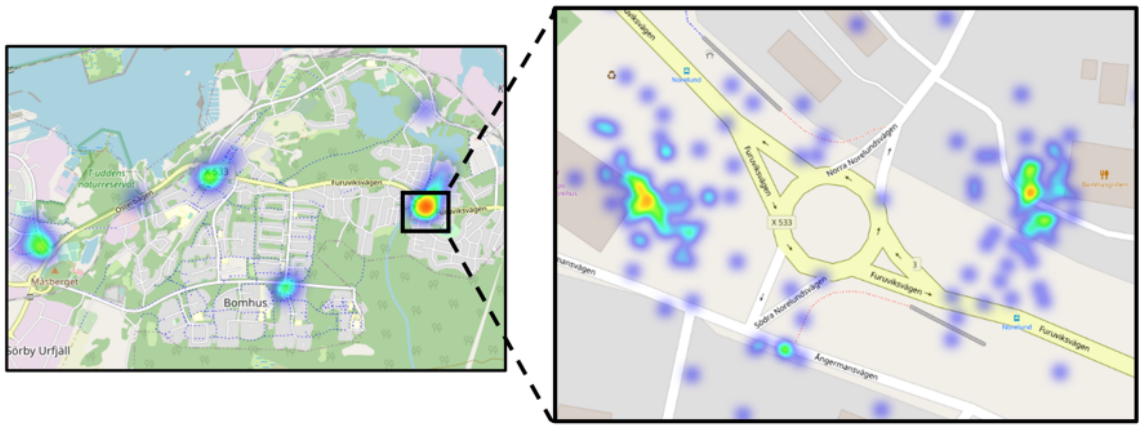
The dashboard (Figure 3) was a cloud-based web service accessible through a web browser. It was developed in Python (Python Software Foundation) using Dash and the Flask web framework. Heat map visualizations were implemented using the Leaflet library. Its main purpose was to provide heat maps of aggregated GPS-tagged data collected from the app along with basic metadata filtering functionalities (eg, date range and photo category). Additionally, it included a photo gallery for quick inspection of the collected data, as well as simple statistical plots and visualizations. The app and dashboard were developed by the Multimedia Understanding Group, Department of Electrical and Computer Engineering, Aristotle University of Thessaloniki, Greece.

XSL•FO
RenderX

Figure 3. The dashboard. Top: heat map visualization used to identify hotspot areas. Bottom: picture gallery.

Phase 1: Identification of Hotspot Areas Using the App and Dashboard

The study started with a session, during which researchers helped the participating children to install the app on their own smartphones. After downloading the app, children registered and answered the in-app questionnaire. Participants then received information from the researchers on how to use the app, including how to take pictures of outdoor food advertisements. They were instructed to avoid taking pictures where people's faces were visible and to avoid taking pictures at their home address. Moreover, participants were informed that the study duration was 2 weeks and that they should take a minimum of 5 pictures of outdoor food advertisements per day, but only the ones that they encounter while living their normal lives (ie, not go out of their way to find food advertisements). Participants were instructed that they could photograph the same advertisement multiple times if they encountered it on different occasions (eg, seeing it daily on their way to school), but only once per occasion. Finally, participants were instructed on what constitutes an outdoor food advertisement with examples (Figure 4). Advertisements in public transportation systems, such as in the subway or on buses, as well as general spaces in shopping malls, were considered as outdoor advertisements, whereas in-store advertisements were not.



XSL•FO
RenderX

Figure 4. Different types of physical food advertisements common in the Swedish context that were considered in the study.

After 2 weeks of data collection, areas where the children reported many food advertisements, so-called "hotspot areas," could be identified via the web-based dashboard (Figure 5). An area was classified as a hotspot if more than 5 pictures of food advertisements were located within a ~50 m radius.

Figure 5. Illustration of the heat maps used to identify hotspot areas at 2 different zoom levels (displayed in the web-based dashboard).

Phase 2: Complementary Researcher Data Collection

Prior to mapping all food advertisements within the identified hotspot areas, the researchers conducted a training session to ensure consistency and reduce the risk of observer bias. During the training session, the 2 researchers independently mapped a nonhotspot area to ensure a similar approach to mapping of advertisements. Any differences in mapping strategies and definitions were discussed, resulting in a more clearly defined food advertisement mapping protocol.

After the training session, each hotspot area identified through the dashboard was converted to a square-shaped hotspot buffer, measuring either 100×100 m or 250×250 m, depending on the number and spatial distribution of pictures taken by children in that area. These buffers served as guides for researchers, indicating where to take pictures of food advertisements. Between June 7 and June 14, 2022, a total of 2 researchers systematically visited each buffer and photographed every food advertisement in all hotspot buffers using the app.

Picture Annotations

An annotation scheme previously developed by the research group [28] was adapted for this study and used as a guideline for annotating the collected pictures. All pictures of food advertisements taken by the researchers in the hotspot areas were annotated based on the content of the following foods: UPFs (including pizza, burgers, kebab, sweet snacks, salty snacks, readymade meals, sugary cereal, sweetened dairy products, sugary drinks, and artificially sweetened beverages; a full list of food and beverages included in the category is available in Multimedia Appendix 1), fruits, berries, and/or vegetables, and fish and/or other seafood. If an advertisement illustrated a meal, more than one-third of the meal had to contain fruits, berries, or vegetables to be annotated as containing fruits, berries, or vegetables (eg, salad on a hamburger or a berry on top of a dessert did not meet the criteria). Logos of well-known fast-food restaurants were annotated as fast food, whereas logos of grocery stores were not assigned to any specific food category. A single image could include multiple categories, for example, both UPFs and fruits, berries, or vegetables.

XSL•FO
RenderX

Two trained nutritionists (PF and SS) annotated all pictures independently using the VIA annotation software for images, audio, and video (Visual Geometry Group, University of Oxford). The pictures were presented in a random order to reduce the risk of location-related bias. Annotation disagreements were discussed until consensus was reached between the 2 researchers. Following this process, the categories fruits, vegetables, and/or berries and fish and other seafood were combined into the composite category "fruits, vegetables, berries, and seafood" (FBVS). Subsequently, 1 trained nutritionist (SS) annotated all pictures to identify the presence of price promotions (eg, discounts, multibuy offers, or super-size deals).

Statistical Analysis

All statistical tests were performed using R software (R Foundation for Statistical Computing). The hypothesis and analysis methods were specified before data collection.

The Pearson chi-square test was selected as the analysis method to compare the proportion of different food advertisements, due to all cells having more than 5 observations. The chi-square tests were performed to compare the proportions of advertisements containing UPFs, FBVS, and price promotions between the included schools based on (1) in what city the school was located (larger vs smaller city) and (2) the SES of the area in which the school was located (low vs high SES). For the comparison based on city size, the 2 schools in Gävleborg were compared against the 2 schools in Stockholm. For the comparison based on SES, only the 2 schools in Stockholm were compared, since there was no clear difference in SES between the 2 areas in Gävleborg.

To evaluate interrater agreement between the 2 researchers' annotations, Cohen κ was used. κ value of <0.21 was interpreted as "no agreement," 0.21‐0.39 "minimal agreement," 0.40‐0.59 "weak agreement," 0.60‐0.79 "moderate agreement," 0.80‐0.90 "strong agreement," and >0.90 as "almost perfect agreement" [33]. The interrater analysis was performed prior to the consensus discussion between the 2 researchers.

Ethical Considerations

This study was approved by the Swedish Ethical Review Authority (DNR 2021-06800-01). Prior to participation, the researchers visited children in their classrooms to provide them with detailed information about the study, including what it means to participate, that participation is voluntary, and that they are free to withdraw consent at any time. If a participant chose to withdraw their consent, they could also request the deletion of all their collected data. Children were also provided with information letters with consent forms for both themselves and their legal guardians to sign if they agreed to participate. Other than providing signed consent, there were no additional inclusion or exclusion criteria. As compensation, individuals received 1 cinema ticket for their participation, regardless of the number of pictures submitted, once the data collection period was completed. To ensure participant privacy, all collected data were pseudonymized. Upon registration in the app, each participant was automatically assigned a random username, which was linked to their uploaded data within the data collection system. As a result, the data remained fully anonymous within the system. However, a separate key file containing the link between usernames and participants' names and schools was securely stored outside the data collection system. This file was accessible only to the research team and was used exclusively to identify users who might have uploaded inappropriate content, such as images containing identifiable personal information, if necessary. All uploaded data were stored on secure servers, accessible only by selected members of the research team. Submitted pictures were reviewed, and pictures not meeting the study's criteria (eg, those unrelated to outdoor food or beverage advertisements) were permanently deleted.

Results

Participant Characteristics (Phase 1)

A total of 46 children participated in the study, and they collected a total of 1308 pictures of food and beverage advertisements using the app. The participant characteristics and the number of pictures taken by the participants in different areas can be seen in Table 1.

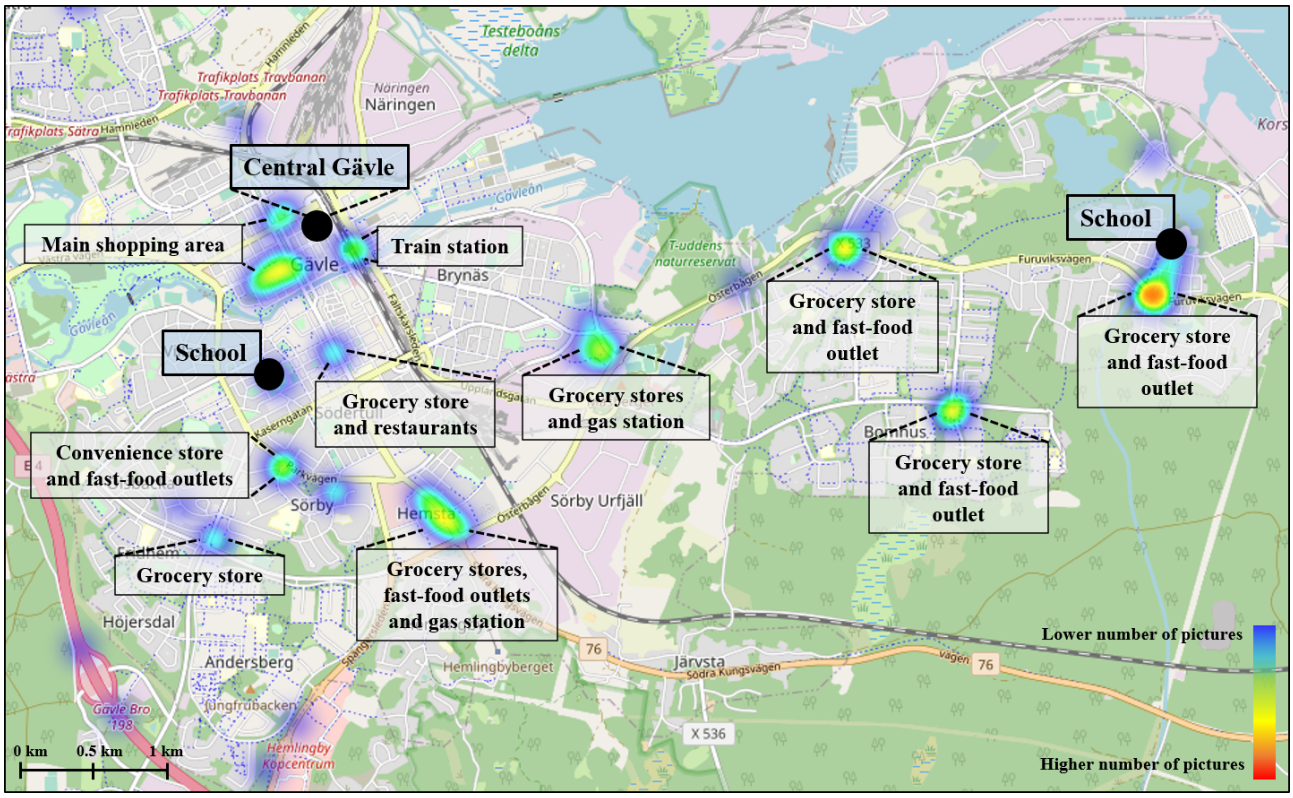
[b]Data missing for 4 participants in Östermalm, 1 participant in Södertälje, and 1 participant in central Gävle.



[c]Including pictures that were not in the scope of the study.

Characteristics of the Identified Hotspot Areas (Phase 1)

Across the 2 counties, 34 hotspot areas were identified using the tool, covering a total area of 740,000 m^2 (74 hectares). At least 1 hotspot area was identified near each school. These areas typically included local grocery stores, convenience stores, and/or fast-food outlets. In Gävleborg and Södertälje, additional hotspot areas were identified further from the schools, also containing similar types of food establishments. Both locations also had hotspot areas located in larger shopping areas. In central Stockholm (Östermalm school), hotspot areas were primarily concentrated in and around subway stations used by children, as well as in shopping malls and outdoor shopping areas. Figure 6 presents a map of the hotspot areas in Gävleborg extracted from the dashboard, along with examples of the types of establishments identified within these areas. Corresponding maps for Stockholm (Östermalm and Södertälje) are provided in Multimedia Appendix 2.

Figure 6. Map depicting the identified hotspot areas in Gävleborg, along with the types of establishments located within each area. The map was extracted from the research dashboard, with labels manually added to indicate the specific establishments present in the areas. The color gradient reflects the number of images associated with each hotspot, ranging from dark blue (indicating a low number of images) to red (indicating a high number of images).

Mapping of Hotspot Areas by the Researchers (Phase 2)

A total of 2955 pictures were taken during the food advertisement mapping activity conducted by the researchers. The number and total size of the identified hotspot areas as well as the number of pictures taken in the hotspot areas were greater in Stockholm compared to Gävleborg (Table 2). However, the mean number of pictures taken per hectare was similar in the 2 counties (42 pictures per hectare in Stockholm vs 37 pictures per hectare in Gävleborg).

Table . Presentation of the number and the size of the hotspot areas per city and school and the number of pictures taken by the researchers in each of the hotspot areas.

School	Hotspot areas, n/N (%)	Size (hectare)	Pictures, n/N (%)	Pictures per hectare
Stockholm	22/34 (64.7)	46.5	1948/2955 (65.9)	41.9
Östermalm	14/34 (41.2)	28.3	1350/2955 (45.7)	47.8
Södertälje	8/34 (23.5)	18.3	598/2955 (20.2)	32.8

Proportions of Different Foods in Advertisements

UPFs

The analysis of the pictures of food advertisements taken by the researchers in all hotspot areas combined showed that 77.5% (2291/2955) of all food advertisements advertised UPFs. When comparing hotspot areas in Stockholm against hotspot areas in Gävleborg, no significant difference was found in proportion of UPFs being advertised (Stockholm: 1505/1948, 77.3% vs Gävleborg: 786/1007, 78.1%; χ^2_1=0.2; *P*=.62). However, a significant difference was observed in the proportion of UPFs advertised between the low- and high-SES areas in Stockholm, with a higher proportion in the high-SES area (Södertälje: 443/598, 74.1% vs Östermalm: 1063/1350, 78.7%; χ^2_1=5.0; *P*=.03).

Fruits, Vegetables, Berries, and Seafood

Overall, 20.8% (616/2955) of all food advertisements promoted FBVS. The proportion of FBVS advertisements was higher in Stockholm compared to in Gävleborg (Stockholm: 445/1948, 22.8% vs Gävleborg: 171/1007, 17%; χ^2_1=13.8; *P*<.001) and in the high-SES area in Stockholm compared to the low-SES area (Södertälje: 116/598, 19.4% vs Östermalm: 329/1350, 24.4%; χ^2_1=5.8; *P*=.02).

Price Promotions

Of all food advertisements in all areas combined, 23.6% (697/2955) included a price promotion. The proportion of advertisements including price promotions was slightly higher in Stockholm compared to Gävleborg (Stockholm: 490/1948, 25.2% vs Gävleborg: 207/1007, 20.6%; χ^2_1=7.8; *P*=.005). No difference in the proportion of price promotions was found when comparing the low- and high-SES areas in Stockholm (Södertälje: 164/598, 27.4% vs Östermalm: 326/1350, 24.1%; χ^2_1=2.4; *P*=.12).

Of all price promotions in all areas combined, 74.3% (518/697) advertised UPFs (compared to 1773/2258, 78.5% of advertisements without a price promotion; χ^2_1=5.4; *P*=.02). The proportion of price promotions that advertised UPFs was significantly higher in Stockholm compared to Gävleborg (Stockholm: 376/490, 76.7% vs Gävleborg: 142/207, 68.6%; χ^2_1=5.1; *P*=.03). There was no significant difference in the proportion of price promotions promoting UPFs when comparing the low- and high-SES areas of Stockholm (Södertälje: 128/164, 78% vs Östermalm: 248/326, 76.1%; χ^2_1=0.2; *P*=.63).

Moreover, of all price promotions in all areas combined, 20.4% (142/697) advertised FBVS (compared to 472/2258, 21% of advertisements without price promotions; χ^2_1=0.1; *P*=.73). There was a higher proportion of advertisements containing price promotions that advertised FBVS in Stockholm compared to in Gävleborg (Stockholm: 110/490, 22.4% vs Gävleborg: 32/207, 15.5%; χ^2_1=4.4; *P*=.04). A significant difference was also observed when comparing the proportion of price promotions advertising FBVS between the low- and high-SES areas of Stockholm, with a higher proportion found in the high-SES area (Södertälje: 23/164, 14% vs Östermalm: 87/326, 26.7%; χ^2_1=10.1; *P*=.002).

Interrater Agreement

"Moderate agreement" (κ=0.762) was observed between the 2 raters for the categorization of advertisements advertising UPF out of total food advertisements. "Moderate agreement" was also observed for the categorization of fruits, berries, and/or vegetables (κ=0.720), as well as for the categorization of fish and other seafood out of total foods (κ=0.775).

Discussion

Principal Findings

This study used a novel mHealth tool, comprising an app and a dashboard, to identify hotspot areas where children are exposed to food advertisements. It also examined the content of food advertisements within the identified areas.

Using the tool, a total of 34 hotspot areas were identified. These included transportation hubs, shopping streets and malls, grocery stores, and fast-food restaurants, both in proximity to schools and further away. More than three-quarters of the food advertisements in the hotspot areas promoted UPFs, such as junk food, ready-to-eat meals, sweet and salty snacks, and sweetened drinks. Fewer than one-quarter of the advertisements advertised FBVS. Price promotions were present in nearly one-quarter of advertisements, predominantly targeting UPFs.

Comparison With Prior Work

Data Collection and Analysis Methodology

Previous research has used child-centric approaches using mHealth technology to investigate children's exposure to food advertising. For instance, the Kids'Cam study [34] combined GPS tracking and wearable cameras to objectively capture children's exposure to food environments, providing detailed and comprehensive data on children's exposure to food marketing. While such approaches generate rich information, they are resource-intensive and might raise privacy and data management challenges. This study offers an alternative approach to investigating children's exposure to food advertising, using an app for child-led documentation that is both scalable and privacy-sensitive.

Analysis Outcomes

The dominance of food advertisements for UPFs aligns with findings from Sweden and other countries [15-20]. Given that children's diets remain high in sugar, fat, and salt and low in whole grains, fruits, and vegetables, the current marketing landscape raises concerns [35]. Several countries have introduced policies to restrict unhealthy food marketing in public spaces to limit children's exposure to marketing for unhealthy foods [36,37]. The results of this study suggest that similar measures may be relevant for Sweden.

A higher proportion of UPF advertisements was observed in the high-SES area of Stockholm compared to the low-SES area, contradicting findings from a previous study by our research

XSL•FO
RenderX

group [28]. The earlier study mapped food advertisements in only 1 location per neighborhood (Skärholmen vs Östermalm) and found a higher proportion of UPF advertisements in the low-SES area. In contrast, this study included multiple locations within each area, offering a more comprehensive assessment of advertising exposure. Although the difference was statistically significant (1063/1350, 78.7% vs 443/598, 74.1%; *P*=.03), the high levels in both areas in this study suggest that the primary public health concern is the overall prevalence of UPF marketing, rather than SES-based differences.

Similar to previous studies [15,28], advertisements for health-promoting foods such as FBVS were scarce in the outdoor food advertising landscape. Other categories of health-promoting foods, such as products with whole grains or healthy fats, were not included in this study due to their extremely low prevalence (<1% of the advertisement dataset).

This study also explored price promotions, which are known to increase consumer purchases and are more frequently used for unhealthy foods compared to healthy foods [38]. While this is a recognized marketing strategy, few studies have examined its use in outdoor food advertising. One study conducted in the United States found that 19% of food advertisements around schools included price promotions but did not specify the types of foods promoted [39].

In our study, a significantly higher share of price promotions targeted UPFs in Stockholm compared to Gävleborg. This difference likely reflects the distinct characteristics of the hotspot areas. Hotspot areas in Stockholm often included subway stations with convenience stores, which frequently have price promotions for UPFs, while hotspot areas in Gävleborg more commonly featured grocery stores that generally have price promotions for a broader range of products. Moreover, within Stockholm, price promotions for fruits and vegetables were more prevalent in the high-SES area than in the low-SES area. Stockholm also had a higher overall proportion of price promotions for FBVS compared to Gävleborg. These patterns may reflect differences in consumer demand or retail marketing strategies across neighborhoods and could have potential public health implications. However, the limited number of participants submitting photos, especially in the low-SES area of Stockholm, may affect the representativeness of the identified hotspot areas, and the results should therefore be interpreted with caution.

Strengths and Limitations

A key strength of this study was the use of a smartphone app and accompanying dashboard, which enabled the identification of areas where children were exposed to food advertisements based on their movement patterns. This approach facilitated the identification of areas that would not have been selected by researchers. For instance, children in Södertälje commuted to a shopping center beyond their immediate residential area, illustrating how children often move beyond their local neighborhoods (Multimedia Appendix 2). In Sweden, where public transportation is widely accessible, particularly in urban areas, such mobility among children is common [40]. This behavior-based method captures local context and population characteristics accurately, supporting improved mapping of children's exposure to food advertising.

In addition, using a smartphone app to collect data is a convenient and cost-effective approach for this target group, as nearly all adolescents in Sweden, and in other high-income countries, own a smartphone that they carry with them throughout the day. The app used in the study allows participants to document their everyday environments in real time, minimizing the need for additional equipment or the presence of researchers. However, the approach also depends on participants' motivation, engagement, and memory to take pictures, which can vary considerably between individuals. In-app notifications might encourage continued participation and improve compliance throughout the data collection period.

Given the pilot nature of the study, the participant sample was relatively small with 46 children from 4 schools contributing pictures. In 2 schools, hotspot areas were identified from only 5 to 7 participants. Additional (or different) hotspots might have emerged with a larger group of participants. However, in Östermalm, hotspots identified from the first 6 participants closely matched those observed after all 14 contributed, suggesting that small participant groups can still provide meaningful insights.

One limitation of researcher-led mapping of food advertisements was that this study did not account for the type or size of the advertisements. For example, a large billboard promoting a single product likely has a different impact than a small poster outside a grocery store displaying multiple items. Additionally, the cross-sectional design of the study did not capture potential weekly or seasonal variation in advertising exposure.

Future Research and Implications

In future research, technology-based tools for data collection could be further developed and expanded to provide a more detailed and personalized understanding of the food environment and individual behaviors. For instance, combining outdoor advertising data with information on digital marketing exposure, such as advertisements children encounter on social media, would offer a more comprehensive picture of overall food marketing exposure. This is particularly relevant, given that 86% of Swedish children aged 8 - 19 years use social media daily, and studies indicate that they are frequently exposed to food advertisements in these digital environments [41]. Furthermore, the app could be extended beyond food advertising to capture users' perception of other environmental factors, such as food availability (fast-food restaurants, grocery stores, convenience stores, etc) and accessibility (financial and geographic). The app could also be used to record dietary habits (at a group or individual level), such as meals, snacks, and beverage consumption. Incorporating these additional data types would enable a more holistic assessment of food environments and their influence on individual behavior. Additionally, privacy-preserving features implemented in the app, such as automatic face blurring before transmission, could further improve usability and user trust and boost engagement and long-term use.

In parallel, the dashboard could be adapted accordingly to provide additional heat maps for the new environmental factors and behaviors, as well as additional analytics for examining the associations between food environment and population

XSL•FO
RenderX

behaviors (eg, by visualizing clusters of different factors on the same map). Similarly, the dashboard could be further developed to present local evolvement over time, for example, comparing data for weekdays and weekends or tracking changes in food advertisements in any given area throughout the year and across different advertising campaigns (eg, it would be expected that different types of advertisements and offers would be present in periods like Halloween or Easter). Automating the identification and classification of advertisement types using machine learning techniques could potentially improve objectivity, accuracy, and efficiency. Applying analytics at the individual level, instead of aggregated, could enable the potential of the dashboard as a tool for personalized guidance. Finally, future research could investigate whether pictures taken by children could substitute those taken by researchers.

Conclusions

Using a novel, child-centered mHealth tool combining a smartphone app and a dashboard, this study identified local food advertising hotspots. Within the identified hotspot areas, 77.5% (2291/2955) of food advertisements promoted UPFs, while only 20.8% (616/2955) featured FBVS. Price promotions were found in 23.6% (697/2955) of advertisements, with the majority promoting UPFs. The proportion of UPF advertisements was high, and FBVS low, across all areas, regardless of city size or SES. These findings reveal a food marketing landscape misaligned with dietary guidelines, underscoring the need for policy action and further research.

Acknowledgments

The authors would like to thank all the teachers and principals who have been involved with the study. This study would not have been possible without the teachers who made time for us in their already busy schedules. The authors also sincerely want to thank the Multimedia Understanding Group, led by Professor Anastasios Delopoulos at Aristotle University of Thessaloniki, for providing the digital tools that were essential for data collection and analysis in this research. ChatGPT, GPT-4 version, from OpenAI (2023), was used to improve the clarity and grammar of parts of the manuscript. No content was generated that relates to the results, interpretation, or conclusions of the study.

Funding

This study was funded by FORTE—the Swedish Research Council for Health, Working Life and Welfare (2021-00518), and by the European Union's research programs (grants 2022-1-SE01-KA220-SCH-0000899 [FoodShift Pathways] and 101104618 [PREVENT—Empowering Childhood Health, Preventing Obesity: Go Healthy for a Bright Future]). Views and opinions expressed are, however, those of the authors only and do not necessarily reflect those of the European Union or the European funding agencies.

Data Availability

The nonpicture datasets generated or analyzed during this study are not publicly available because they may require guidance for proper use but are available from the corresponding author upon reasonable request. The picture datasets are not publicly available due to privacy concerns and in accordance with the ethical approval for this study (DNR 2023-01085-01).

Abstract

Background: Exposure to circadian entrainers, such as sunlight, positively impacts sleep architecture, while exposure before bedtime to circadian disruptors, such as artificial light and smartphone use, can negatively affect sleep. However, real-world evidence from longitudinal observational studies that simultaneously capture these factors alongside electroencephalography-derived sleep stages remains limited.

Objective: This study aimed to investigate the effects of specific environmental and behavioral factors on sleep metrics and architecture by using sensor-based measurements over 7 consecutive days. Specifically, it examined day-to-day associations between (1) daytime sunlight exposure and (2) prebedtime artificial light exposure and smartphone use with selected sleep outcomes on the following night.

Methods: A total of 21 participants from the Jerusalem metropolitan area were monitored continuously using the Dreem wearable electroencephalography for sleep staging, HOBO data loggers for light exposure, the wGT3X+ triaxial accelerometer for physical activity, and a dedicated mobile app to record smartphone usage. Sleep outcomes included total sleep time (TST), sleep onset latency (SOL), and the proportions of light sleep (N1) and deep sleep (N3). Sunlight exposure was defined as the number of hours above 1000 lux during daytime, and artificial light and smartphone use before bedtime were quantified as the duration of exposure accumulated in the 2 hours preceding sleep onset. Linear mixed-effects models with a random intercept at the individual level estimated the associations between these exposures and next-night sleep outcomes, adjusting for step count and other individual covariates.

Results: The average TST was 420 (SD 85) minutes, and SOL averaged 17.6 (SD 18) minutes. Light sleep (N1) represented 6.6% (SD 2.1%) of sleep, and deep sleep (N3) accounted for 20.1% (SD 7.6%). Each additional hour of daytime sunlight exposure was associated with an increase of 10.67 (95% CI 0.6-20.7) minutes in TST the following night and with a 0.3 (95% CI –0.6 to –0.0) percentage-point decrease in light sleep (N1) percentage. No associations were found between evening artificial light exposure and sleep outcomes, while each minute of smartphone use before bedtime was linked to an increase in SOL of 0.2 (95% CI 0.0-0.4) minutes.

Conclusions: These findings emphasize the importance of daylight exposure for circadian alignment and the potential sleep-disruptive effects of evening digital engagement. This study demonstrates the feasibility and value of integrating wearable electroencephalography and environmental and behavioral sensors in naturalistic settings to uncover behavioral and environmental correlates of sleep architecture.

Introduction

Sleep Dynamics

Sleep is a fundamental biological process that is crucial for maintaining overall health and well-being, playing a vital role in cognitive function, emotional regulation, metabolism, and immune system performance [1]. Insufficient or poor-quality sleep has been associated with a wide range of health issues, including cardiovascular and metabolic dysfunction, mental health disorders, cognitive decline, and increased all-cause mortality [2-5].

Sleep is a dynamic process made up of distinct stages, which collectively determine its architecture. Sleep is generally divided into non–rapid eye movement sleep, which includes light (stage 1 sleep [N1] and stage 2 sleep [N2]) and deep sleep (stage 3 sleep [N3]), and rapid eye movement (REM) sleep [6]. Each sleep stage serves critical functions: light sleep allows transitions from wakefulness into sleep and subsequent sleep stages, deep sleep supports physiological restoration and recovery, and REM sleep contributes to cognitive processing and emotional regulation [7,8]. Sleep occurs in ultradian cycles that alternate between non–rapid eye movement and REM sleep approximately every 90 minutes [9]. The first cycles are characterized by a higher prevalence of deep sleep, while REM sleep becomes increasingly prominent in the later cycles [6]. These cyclical processes are regulated by circadian rhythms of the body's internal clock, which synchronizes sleep timing with environmental cues such as light and darkness [10].

Circadian Entrainment and Disruption

Circadian entrainment refers to the alignment of the internal circadian clock with external environmental cues, such as the light-dark cycle of the day. Sunlight is the most powerful entrainer, as it modulates the release of melatonin, a hormone secreted by the pineal gland that regulates the timing of sleep and wakefulness [10]. During daylight, sunlight suppresses melatonin secretion, promoting wakefulness and alertness; as light diminishes in the evening, melatonin levels rise, facilitating sleep onset [11]. Adequate daytime sunlight exposure therefore strengthens circadian entrainment, leading to earlier sleep onset and longer total sleep time (TST) [12]. Consistent evidence shows that more time spent outdoors, exposed to natural light, is associated with a stronger circadian rhythm and better mood and sleep outcomes [13,14].

Conversely, circadian disruption occurs when external factors or individual behaviors cause misalignment between endogenous circadian rhythms and the external environment [15]. This misalignment may also disrupt the synchronization between the body's central clock, located in the suprachiasmatic nucleus, and peripheral clocks in tissues and organs, potentially contributing to dysregulation of physiological and behavioral rhythms such as hormone release, metabolism, and the sleep-wake cycle [10,15]. A key contributor to circadian disruption is artificial light at night, particularly the blue light emitted from digital screens and smartphones. This stimulation suppresses melatonin production, which normally supports circadian alignment and promotes sleep propensity, thereby delaying sleep onset and altering sleep architecture [11,16].

Behavioral circadian modulators further influence the alignment or misalignment of circadian rhythms. In addition to blue light exposure, smartphone use before bedtime also provides stimulating content (eg, social media) that may increase cognitive and physiological arousal, activating the hypothalamic-pituitary-adrenal axis and elevating cortisol levels, ultimately interfering with sleep initiation and maintenance [17]. However, there is limited and mixed evidence regarding how and to what extent smartphone use might affect sleep stages, and thus, the topic warrants further investigation [18].

Engaging in regular physical activity, particularly earlier in the day, can promote circadian entrainment by reinforcing the distinction between active daytime and restful nighttime periods [19-21]. Exercise has been associated with improved sleep onset and increased proportions of deep sleep (N3), whereas intense physical activity close to bedtime may elevate core body temperature and arousal levels, potentially delaying sleep onset and disrupting sleep architecture by reducing REM sleep and increasing light sleep [21,22]. Other health-related behaviors, such as napping, evening food intake, and the consumption of alcohol, caffeine, or medications, can also affect sleep and circadian rhythms by altering metabolism, arousal and sleep pressure, delaying sleep onset, and decreasing deep and REM sleep [23-25].

Gaps in the Literature and Rationale of the Study

Despite the recognized role of environmental and behavioral factors in sleep and circadian regulation, there are gaps in the literature concerning their combined effects on sleep architecture. Regarding the variables examined in the literature, previous studies have mainly focused on either sunlight exposure or artificial light at night in isolation, without considering the additional influence of other behavioral modulators such as smartphone use and physical activity [13,14,26,27]. For instance, time spent outdoors often correlates with higher physical activity, which also impacts sleep [28,29]. Controlling for physical activity is therefore essential when assessing the effects of sunlight exposure on sleep outcomes to avoid confounding effects.

Regarding sleep and circadian health, an increasing number of studies are adopting sensor-based methods to measure sleep and physical activity in both observational studies and clinical trials [30,31]. However, the majority of these studies rely on accelerometry to assess sleep outcomes, which, while useful for estimating general sleep metrics (eg, TST and sleep efficiency [SE]), lacks the ability to provide detailed insights into its architecture and sleep stages [32-36]. There is a scarcity of research using wearable electroencephalography devices in real-life settings outside controlled experimental environments, which offer more precise measurements of sleep stages compared to other sensors [32,37,38]. Finally, regarding study

XSL•FO
RenderX

designs, only a minority of these studies have used longitudinal frameworks with repeated measures to capture the day-to-day variability in environmental exposures, behaviors, and sleep outcomes over multiple days of tracking [39,40]. In contrast, the majority of studies have adopted cross-sectional designs, limiting their ability to move beyond mere associations and understand causal relationships through assessment of within-person processes [39,40].

Objectives

Our study addresses gaps in the literature by conducting a 7-day sensor-based investigation assessing sunlight exposure, artificial light at night, and behavioral circadian modulators. Through continuous light monitoring, smartphone use tracking, and physical activity measurement, we aim to comprehensively evaluate the effects of circadian entrainment and disruption on electroencephalography-based sleep metrics. This research not only fills a critical gap in the existing literature but also has practical implications for developing interventions and guidelines to enhance sleep health through the management of light exposure and sleep-hygiene behavioral practices.

In this study, we selected a priori TST, sleep onset latency (SOL), light sleep (N1), and deep sleep (N3) as main sleep outcomes, based on their theoretical relevance to sleep and circadian health. TST is the most used sleep measure in the literature and reflects overall sleep duration [38]. SOL measures the time taken to fall asleep, reflecting the ease of initiating sleep and showing sensitivity to presleep behaviors that may delay sleep onset [41]. N1 marks the transition from wakefulness to deeper sleep stages in each cycle and serves as an indirect marker of sleep fragmentation and efficiency [42]. N3, the most restorative sleep stage for physical health, responds strongly to daily activity and circadian alignment, making it valuable for evaluating how behavioral factors affect sleep [19,42].

First, we aim to quantify the effect of sunlight exposure during the day, as a proxy for circadian entrainment, on sleep. Second, we seek to measure the impact of potential circadian disruptors, such as exposure before bedtime to bright artificial light and smartphone use, on sleep. We hypothesize that (1) longer sunlight exposure will be associated with longer TST, a lower percentage of light sleep (N1), and a higher percentage of deep sleep (N3) and (2) exposure to bright artificial light and smartphone use close to bedtime will be associated with shorter TST, increased SOL, a higher proportion of light sleep (N1), and a lower percentage of deep sleep (N3).

Methods

Participants and Study Design

Our study included 21 participants from the Jerusalem metropolitan area (Israel) and was conducted from May 2023 to July 2024. Participants were monitored over a 7-day period using wearable sensors and smartphone apps.

Given the small sample size, a quota sampling approach was adopted to recruit participants for this study, allowing for diversity and representation across key demographic groups (ie, household income, age, and gender) without requiring strict proportionality to the broader population.

Recruitment was conducted in 2 stages: first, an Israeli panel company contacted individuals from their preestablished pool of volunteers who had previously signed up for scientific studies. The panel company confirmed participants' willingness to participate and screened them for eligibility through a questionnaire based on the study's recruitment criteria. The main inclusion criteria required participants to be aged between 18 and 65 years and to reside in the metropolitan area of Jerusalem. Exclusion criteria included engaging in any form of shift work, having mobility limitations, significant health conditions, or a clinical diagnosis of sleep or mental health disorders. In the second stage, a research assistant followed up with eligible candidates by phone to explain the study in greater detail, further inviting them to participate and initiating the scheduling of data collection.

Following initial sampling, eligible participants were onboarded through a home visit conducted by a research assistant, marking the start of the data collection period. During this visit, the research assistant administered an entry online questionnaire collecting key demographic information and explained the study protocol, emphasizing the significance of their involvement in studying urban health. Participants received an information sheet outlining the sensor charging and wearing schedule, along with a contact number for questions and support.

Ethical Considerations

The study received ethical approval from The Hebrew University of Jerusalem's Committee for the Use of Human Subjects in Research (approval number 22022023; February 2023). All participants provided informed consent prior to participation and could withdraw at any time without consequence. The study adhered to the General Data Protection Regulation and institutional ethical standards for human research, ensuring compliance with data storage, sharing, and confidentiality requirements. All collected data were pseudonymized before analysis, and identifiable information was stored separately in secure, password-protected databases. Upon successful completion of the 7-day protocol, participants were compensated with ILS 300 (US $104) as an acknowledgement of their cooperation and motivation to adhere to the study.

Sensor-Based and Mobile Measures

Sleep Assessment

Each night, participants' TST, SE, SOL, wake after sleep onset, and the duration of sleep stages (N1, N2, N3, and REM) were assessed using the Dreem Headband, a wearable electroencephalography device (Figure 1). The headband has been validated against polysomnography, the gold standard for sleep measurement, demonstrating high accuracy in sleep staging when compared to manual scoring by sleep experts [32]. This nonintrusive device provides reliable sleep assessment in real-world, home settings, providing an advantage over actigraphy devices, which are unable to differentiate sleep stages accurately [32,35,36].

XSL•FO
RenderX

Figure 1. Study Sensors: (1) Dreem 3 Headband (Beacon Biosignals); (2) wGT3X+ triaxial accelerometer (ActiGraph); (3) HOBO Data Logger (Onset Computer Corporation).

Light Exposure

Participants wore a HOBO Data Logger daily, attached to the collar of their clothing with a safety pin. This positioning was intended to approximate light exposure at the level of the eyes, where light signals are transmitted from the retina to the suprachiasmatic nucleus, the central circadian pacemaker [33]. The timing, duration, and intensity of light exposure were used to assess participants' daily circadian entrainment to sunlight and potential disruption from artificial light at night. Based on previous research, daytime sunlight exposure was operationalized as the total duration (in hours) of exposure to light intensity above 1000 lux across the day [43]. Before bedtime, artificial light exposure was defined as the total duration (in minutes) of exposure to light intensity above 30 lux across varying time windows in the 2 hours preceding sleep onset.

Physical Activity

Participants carried a wGT3X+ triaxial accelerometer on a waist belt on the right hip every day during waking hours. The accelerometer was used to assess various physical activity metrics, including step count (in units of 1000 steps), metabolic expenditure, time spent in moderate to vigorous physical activity, light physical activity, and sedentary time. Nonwear periods were identified and excluded using the Choi algorithm [44]. Physical activity metrics were calculated using established criteria, such as the Freedson Adult VM3 cut-points (2011) and the Crouter 2R regression equation [45,46]. After preliminary analyses, we selected step count over the other physical activity metrics for its greater explanatory power in capturing sleep outcome variability.

Smartphone Usage Tracking App

A designated app installed on participants' smartphones tracked the total time spent using the smartphone and the time spent using apps for the whole data collection period. The app was developed at the Department of Geography and the Center for Urban Innovation at the Hebrew University of Jerusalem. For analysis, apps were classified into categories (eg, social media, productivity, and entertainment), and the original app names were removed to ensure participant privacy. From these reports, we computed for each day the total number of minutes spent using each app category. However, preliminary analyses revealed no meaningful differences between total smartphone use and the use of social media apps in explaining sleep outcomes variability. Therefore, for our main analyses, we used total smartphone use, as it encompasses all types of smartphone activity, offering a more inclusive measure.

Statistical Methods

We used linear mixed-effects models with a random intercept at the individual level to examine the effects of circadian entrainment and disruption on sleep outcomes. This approach accounted for the nested hierarchical structure of the data (successive nights nested within participants) and controlled for between-subject variability in baseline sleep patterns.

The outcomes modeled were TST, percentages of N1 and N3, and SOL. To test the first hypothesis, that higher daytime sunlight exposure is associated with better sleep outcomes, we used daily sunlight exposure (measured in hours) as the primary predictor, with daily step count as a covariate to control for potential confounding from physical activity. To test the second hypothesis, we examined whether exposure to artificial light and smartphone use before bedtime negatively affect sleep outcomes. The primary predictors were artificial light exposure (measured as minutes of exposure above 30 lux [ie, dim light], a physiologically relevant threshold used in previous protocols [47]) and smartphone use (in minutes) in the 2 hours before bedtime. Step count in the same time window was included as a covariate to control for potential confounding from physical activity. Before selecting the 2-hour window for artificial light, we conducted a sensitivity analysis across different time windows before bedtime (5, 10, 15, 20, 25, 30, 60, and 120 minutes) to assess potential differences in their associations with sleep outcomes. As no meaningful differences were detected across these intervals, we proceeded with the most inclusive duration of 2 hours before bedtime to capture potential cumulative effects and maximize variability.

XSL•FO
RenderX

For covariate selection, we initially considered a broad set of potential confounders, refining the final model based on preliminary analyses (Table 1). The final selected covariates for all models included age group (25-29 years and 30-65 years), gender (female and male), household income per unit of consumption (low: ILS ≤5550 [US $1900] and high: ILS >5550 [US $1900]), weekday vs weekend, and season (spring, summer, autumn, and winter) to account for possible seasonal influences on sleep and light exposure.

Table 1. Participants' characteristics[a].

Characteristics	Values, n (%)

City center	7 (33)

[a]N=21.

Due to constraints in data availability, we tested separate models for our 2 hypotheses rather than combining all the predictors into one comprehensive model. Including all predictors in a single model would have reduced the sample size, as observations with missing data on any predictor would have been excluded, affecting model power and stability. By analyzing these factors in independent models, we maximized the use of available data to evaluate each predictor's relationship with sleep outcomes. No adjustment for multiple comparisons was performed, as models were specified a priori and focused

XSL•FO
RenderX

on a limited set of exposures and outcomes. Findings are therefore interpreted cautiously in light of the modest sample size and correlated predictors and outcomes. Statistical analyses were conducted using the R software (version 4.0.2; R Core Team; 2017).

Results

Descriptive Statistics

Of the 21 participants, 14 (67%) were female, and 11 (52%) were aged between 30 and 65 years; 16 (76%) were Israeli citizens, 9 (43%) had university education, and 12 (57%) reported a lower household income (ILS ≤5550 [US $1900]). See Table 1 for additional details.

The average TST was 420 (SD 85.4) minutes per night, ranging from 120 to 667.5 minutes across specific nights among participants. SOL averaged 17.6 (SD 18) minutes, with a range of 0.5-99 minutes across specific nights. N1 sleep accounted, on average, for 6.6% (SD 2.1%) of TST, ranging from 2.6% to 13.1%. N3 sleep reached, on average, 20.1% (SD 7.6%) of TST, with a range of 5.2%-51.1% across specific nights. See Table 2 for more sleep outcomes.

Table 2. Descriptive statistics on sleep outcomes.

Outcome	Mean (SD)	Range
TST[a] (min)	420 (85.4)	120-667.5
WASO[b] (min)	29.1 (25)	1-143
Sleep efficiency (%)	89.4 (6.7)	66.2-97.9
Sleep onset latency (min)	17.6 (18)	0.5-99
N1[c] (%)	6.6 (2.1)	2.6-13.1
N2[d] (%)	48 (7.6)	22.1-65.6

Participants spent an average of 1.2 (SD 1.6) hours exposed to sunlight, with a range from 0 to 8.3 hours across specific days across participants. Time spent using smartphone apps was 169 (SD 178) minutes per day on average, with social apps accounting for 44.0% (SD 21.9%) of that time. Daily step count averaged 6033 (SD 3779), ranging from 57 to 15,516 steps across specific days. See Table 3 for further details.

Sunlight Exposure and Sleep

In this study, the association between daily sunlight exposure (in hours) and key sleep outcomes the following night was analyzed, as shown in Table 4. Each additional hour of sunlight exposure was associated with an estimated increase of 10.7 (95% CI 0.6-20.7) minutes in TST. In terms of sleep architecture, sunlight exposure was associated with a decrease in the percentage of N1 sleep by 0.3 (95% CI –0.6 to –0.0) percentage points, while no association with N3 sleep was detected.

Table 4. Associations between sunlight exposure and sleep outcomes (116 observations; 21 participants).

A separate model was estimated to adjust for physical activity, measured as daily step count (per 1000 steps). This adjustment reduced the analytic sample by 40 observations, including all data from 2 participants, warranting separate estimation. In this model, the association between sunlight exposure and TST was unchanged (each additional hour of sunlight being associated with an increase of 11.6 (95% CI –0.5 to 23.8) minutes in TST, although the CI included 0. In contrast, higher daily step count was associated with longer TST, with an estimated increase of 6.1 (95% CI 1.0-11.1) minutes per additional 1000 steps. Further details are provided in Multimedia Appendix 1.

Circadian Disruptors and Sleep

In examining the impact of circadian disruption on sleep outcomes, we evaluated the associations of artificial light exposure, step count, and smartphone use recorded in the 2 hours prior to bedtime with key sleep outcomes the following night, as shown in Table 5. While no associations were observed between artificial light exposure or step count and TST, N1, or N3 sleep stages, smartphone use showed an association with SOL, where each additional minute of smartphone use before bedtime was associated with an increase in SOL by 0.2 (95% CI 0.0-0.4) minutes.

Discussion

Principal Findings

Our findings support the first hypothesis that higher daytime exposure to sunlight is associated with increased TST and a reduction in light sleep (N1). Specifically, each additional hour of sunlight exposure was linked to an increase of approximately 10.7 (95% CI 0.6-20.7) minutes in TST and a decrease of 0.3 (95% CI –0.6 to –0.0) percentage points in N1 sleep. These results align with previous research suggesting that natural light exposure strengthens circadian entrainment, leading to improved sleep duration and quality [12-14]. Similarly, the potential circadian entrainment from increased sunlight exposure might have contributed to reduced N1, suggesting a quicker transition from wakefulness into deeper sleep stages [42,48]. This reduction in N1 could reflect enhanced circadian alignment, promoting a smoother progression into the other sleep stages. However, we did not observe an association between sunlight exposure and deep sleep (N3), which contrasts with our initial hypothesis. While some studies have reported that natural light exposure can enhance deep sleep [49], our results suggest that the relationship may be more nuanced. It is possible that factors such as individual differences in circadian sensitivity, genetic predispositions, or, most importantly, the timing of sunlight exposure might play a role [49-51]. The effect of sunlight

XSL•FO
RenderX

exposure on N3 might be more pronounced when it occurs shortly after wake-up time, when the sun's blue-enriched morning light exerts stronger phase-advancing effects on circadian entrainment [51,52]. Using a daily cumulative indicator of sunlight exposure could average out these timing-specific effects, potentially obscuring its impact on deep sleep, which should be further examined in future sensor-based research.

After controlling for daily step count, the point estimate of the association between sunlight exposure and TST was even slightly increased, suggesting the absence of substantial confounding by physical activity. The CI of the association included 0 in this last model, likely due to reduced statistical power from the smaller sample of 76 observations with both sunlight and physical activity data, compared to 116 in the previous model. Increased physical activity during the day might have extended TST by promoting a greater need for physiological recovery, enhancing overall sleep drive [53]. On the other hand, the independent association between sunlight exposure and a decrease in N1 sleep remained fully apparent in the model controlling for step count with fewer observations, highlighting the unique role of natural light in regulating sleep architecture beyond physical activity levels. This finding is noteworthy because it isolates the effect of sunlight from major confounders like physical activity, which is often correlated with time spent outdoors [28,29]. Additionally, this pattern suggests that physical activity may not mediate the relationship between sunlight exposure and improved sleep architecture, although a formal mediation analysis would be warranted to confirm this interpretation and to clarify the interplay between sunlight exposure, physical activity, and sleep. Remarkably, daily step count, used as a proxy for physical activity, was not associated with N1 or N3 percentages, despite evidence that higher levels of physical activity generally enhance SE and promote more restorative sleep with reduced light sleep and increased deep sleep [19,21,53].

The positive associations between daytime sunlight exposure, physical activity, and better sleep outcomes underscore the importance of natural light and movement for supporting circadian alignment and sleep health. Encouraging daily exposure to natural light and regular physical activity, individually or in combination, could be an effective strategy for improving sleep quality across the general population. These findings support public health recommendations encouraging time outdoors and physical activity to enhance sleep and circadian health, ultimately fostering overall well-being.

Contrary to our second hypothesis, we did not find any association between exposure to artificial light before bedtime and alterations in TST, SOL, or sleep architecture. This finding diverges from prior studies that have reported negative impacts of evening exposure to artificial light on sleep onset, duration, and stages with increases in light sleep and reductions in deep sleep [16,26]. This discrepancy may be due to the relatively low intensity or limited duration of artificial light exposure in our sample, which may have been insufficient to affect sleep architecture. Additionally, individual differences in light sensitivity and circadian preference may influence susceptibility to artificial light's effects on sleep [54]. Furthermore, participants may have exhibited overall good sleep hygiene, with the cumulative benefits of various positive behaviors potentially offsetting any negative impact of artificial light on sleep [55]. Finally, it is also possible that the light sensor was incorrectly worn by some of the participants during the hours just before sleep time.

Regarding smartphone use, while no associations were observed with TST, N1, or N3 sleep stages, an association with increased SOL was detected, indicating that smartphone use before bedtime may delay sleep onset. Since our model controlled for artificial light exposure, this delay likely stems not from light emitted by screens but rather from the arousal-increasing and mentally engaging nature of smartphone activities. This aligns with evidence that smartphone use before bedtime can increase cognitive arousal and hinder the presleep relaxation process critical for facilitating sleep onset [56].

The mixed findings regarding artificial light and smartphone use highlight the complexity of assessing individual sleep behaviors and their impacts. The lack of observed negative effects from artificial light before bedtime could indicate that its impact on sleep may be less pronounced or more individualized than previously thought, underscoring the need for an idiographic approach in future research to capture individual variations in light sensitivity [57]. The association between smartphone use and increased SOL suggests that smartphone engagement before bedtime can interfere with the winding-down process necessary for sleep. This points to the importance of limiting mentally stimulating activities in the evening to promote a smoother transition to sleep. Our findings support the inclusion of recommendations in sleep hygiene guidelines to reduce evening smartphone use as a strategy to maximize sleep and circadian health.

Strengths and Limitations of the Study

A major strength of this study is the use of innovative sensor-based tools to collect objective, high-resolution data on sleep architecture, light exposure, physical activity, and smartphone use in real-world settings. The use of wearable electroencephalography devices provided precise measurements of sleep stages, offering a significant advantage over traditional actigraphy, which cannot accurately differentiate between sleep stages, and an even greater advantage over self-reported sleep assessments via questionnaires commonly used in studies on the environmental determinants of sleep [32]. The continuous monitoring of light exposure using data loggers positioned near eye level allowed for accurate estimation of circadian entrainment and disruption factors. Additionally, the integration of a smartphone app to track usage patterns provided insights into a major behavioral circadian disruptor. The repeated measures design over 7 consecutive days enabled us to capture day-to-day variability and to better identify individual differences, offering a nuanced view of how environmental exposures and behaviors impact sleep architecture over time.

However, the study has several limitations. The short duration and small sample size of the study may limit the generalizability of the findings. While we accounted for seasonal variation, the 7-day monitoring period may have restricted our capacity to fully capture its influence on sleep patterns [39]. Additionally,

XSL•FO
RenderX

the limited sample size prevented us from controlling for sleep autocorrelation, a key component of sleep variability [39,57], and may have limited our ability to detect meaningful associations. Future studies with extended monitoring periods and larger samples are needed to account for temporal dynamics and enhance precision in understanding sleep variability and its determinants.

Due to missing data and limited observations, we were also unable to include all relevant predictors in a single comprehensive model, which restricted our ability to evaluate potential reciprocal confounding effects between the exposures. Furthermore, although smartphone ecological momentary assessments captured several health-related behaviors in our study, excessive missing data prevented us from using these measures to account for behaviors with known disruptive effects on sleep, such as the timing of caffeine, alcohol, medication, and food intake, napping habits, or the use of blue light–blocking lenses or screen filters [23-25]. These unmeasured confounders could have influenced the associations that we observed or our ability to identify associations that we were unable to detect. Finally, the reliance on light intensity measurements without considering the spectral composition of light limited our ability to differentiate between the effects of different light wavelengths on circadian rhythms [16,51]. Including such variables in future studies could improve the accuracy and comprehensiveness of the findings.

Despite these limitations, our study highlights the potential of sensor-based methods in advancing sleep research. By demonstrating the feasibility of integrating multiple wearable devices and a smartphone app to capture detailed environmental and behavioral data, we contribute to the development of ecologically valid approaches to studying sleep and circadian health. Serving as a proof of concept, this approach lays the groundwork for future studies with larger samples and extended monitoring periods, paving the way for more ecologically valid investigations into the complex interactions between environmental exposures, behaviors, and sleep outcomes.

Conclusions

Our findings underscore the beneficial impact of daily sunlight exposure and physical activity on enhancing sleep duration and reducing light sleep, highlighting the importance of natural light and movement for circadian alignment and overall sleep health. While artificial light before bedtime showed no association with sleep, smartphone use was linked to delayed sleep onset, potentially due to its stimulating effects. These results support public health recommendations to encourage outdoor exposure to sunlight and more physical activity while advising limited smartphone use in the evening to improve sleep and circadian health. These insights contribute to a better understanding of the factors influencing sleep architecture and underscore the potential of sensor-based methodologies in advancing sleep research.

Abstract

Background: Emergency department (ED) crowding compromises patient safety and increases clinical workload. Existing crowding metrics capture structural indicators but not how clinicians subjectively experience crowding in real time. Clinician perception may provide a complementary measure.

Objective: This study aimed to examine the concurrent and temporal associations between clinicians' real-time ED perceived crowding (EDPC), captured via a smartwatch-based ecological momentary assessment (EMA) system, and 3 objective crowding metrics: the ED occupancy ratio (EDOR), the National Emergency Department Overcrowding Score (NEDOCS), and the ED Work Index (EDWIN).

Methods: We conducted a prospective observational study over a continuous 449-hour period (November 25, 2024, 7 AM to December 13, 2024, 11:59 PM) in a single tertiary ED operating under reduced bed capacity and attending-only staffing due to a national physician shortage. We enrolled 28 clinicians (5 attending physicians and 23 charge nurses; mean age 36.3, SD 5.9 years; 21 female and 7 male) by voluntary nonprobability sampling. Clinicians recorded EDPC hourly during active shifts on a continuous 0-200 scale anchored to the NEDOCS crowding categories, from "Not Busy" to "Dangerously Overcrowded." All valid ratings within each hourly period were aggregated into a single median EDPC value. Interrater agreement was assessed with the Gwet weighted agreement coefficient (AC2) at hourly time points with at least 2 ratings. Main analyses used Pearson correlations between hourly median EDPC and median EDOR, NEDOCS, and EDWIN. Linear mixed-effects models additionally accounted for repeated ratings within clinicians and clustering at the same hourly time point. Time-lagged correlations were exploratory. Statistical significance was set at α=.05.

Results: Across 1124 scheduled on-duty assessment opportunities, clinicians completed 1100 individual EDPC ratings (response rate 1100/1124, 97.86%). These ratings yielded 449 hourly aggregated EDPC observations, with a median of 2 (IQR 2-3; range 1-4) clinicians contributing ratings per hour. Interrater reliability was substantial (AC2=0.742, 95% CI 0.712-0.772). Objective

XSL•FO
RenderX

metrics were derived from 1846 ED visits. Hourly median EDPC correlated with median EDOR (r=0.542, 95% CI 0.473-0.604; P<.001) and NEDOCS (r=0.483, 95% CI 0.409-0.551; P<.001), but not EDWIN (r=0.060, 95% CI –0.033 to 0.152; P=.20).

Conclusions: We deployed smartwatch-based EMA to capture high-frequency, in situ clinician perceptions during active shifts, potentially reducing susceptibility to retrospective recall bias while minimizing the spatial constraints of traditional survey methods. Hourly median EDPC was moderately associated with EDOR and NEDOCS in this single tertiary ED during an exceptional staffing crisis. The association with EDWIN was less consistent and became significant only after adjustment for time-of-day patterns. The high response rate (1100/1124, 97.9%) supports the short-term feasibility of repeated wearable-based data collection during routine clinical shifts. These findings support further investigation of EDPC as a complementary operational measure but do not establish that it directly measures cognitive workload or predicts subsequent crowding.

Introduction

Problem

Emergency department (ED) crowding compromises the quality of care and increases clinician workload worldwide [1-3]. Crowding occurs when the demand for emergency services exceeds the available capacity of the ED or hospital resources [4], reflecting the combined impact of patient volume, acuity, bed availability, and staffing levels [2,3,5]. An aging population is bringing growing numbers of older patients whose multimorbidities and nonspecific symptoms prolong their length of stay [3,6,7]. Boarding of critically ill patients is a major driver of crowding [8-10], forcing departments to deliver intensive inpatient-level care. Despite this escalating burden, how the clinicians managing it experience crowding in real time remains poorly understood.

Review of Relevant Scholarship

Several metrics quantify different aspects of crowding [11,12]. Recent reviews, however, have emphasized that the performance and interpretability of ED crowding indices vary across hospital types and operational contexts [13], and that no universally accepted gold standard has been established [11-15]. These indices capture structural aspects of crowding, such as bed occupancy, boarding time, and acuity-weighted patient-to-staff ratios [16-18], rather than how clinicians subjectively experience crowding in real time.

Existing indices differ in what they operationalize. The National Emergency Department Overcrowding Score (NEDOCS), the most widely used metric [11,12,15], incorporates multiple operational components, including the number of patients currently in the ED, the number of admitted patients waiting for hospital beds, the total number of hospital beds, the longest waiting time from triage to bed assignment, the longest boarding time, and the number of patients receiving mechanical ventilation [17]. Based on these parameters, NEDOCS categorizes ED status into 6 levels ranging from “Not Busy” (0-20) to “Dangerously Overcrowded” (180-200) [11,12,17]. The ED occupancy ratio (EDOR) also focuses on physical occupancy, comparing active patients with operational beds [16]. Whereas EDOR and NEDOCS are based on patient counts and bed capacity, the Emergency Department Work Index (EDWIN) incorporates patient acuity and staffing levels to reflect the intensity of care required [18].

Clinicians’ subjective perception of crowding has received relatively limited empirical attention [11,14], despite growing interest in how it relates to these objective crowding measures [12,15]. Notably, perceived and objective crowding can diverge: in the original NEDOCS validation study, physicians reported feeling less rushed once the ED became severely overcrowded and all beds were full [17], suggesting that objective crowding may not align with clinicians’ subjective perceptions. This divergence has been repeatedly documented across diverse ED settings [19,20].

In this study, ED perceived crowding (EDPC) refers to clinicians’ real-time subjective perception of ED crowding, distinct from operational crowding, clinical workload, and cognitive workload. These constructs are related but not interchangeable [19], and this study directly measured only clinicians’ perceptions of ED crowding. To operationalize EDPC, we adapted the 6 anchors of the original NEDOCS outcome scale ranging from “Not Busy (0-20)” to “Dangerously Overcrowded (180-200)” as a real-time response scale [17].

Where prior work has captured clinician perception, it has typically relied on convenience samples of discrete time blocks [12,14,17] rather than systematic, repeated measurements across a full shift. In this fast-paced, highly uncertain environment [21], real-time assessment of EDPC may provide complementary operational insights. The role of frontline clinicians is critical to timely care delivery [22,23]; operational metrics alone, however, cannot capture their direct experience of crowding. Recent advances in mobile data collection, particularly ecological momentary assessment (EMA), offer a practical means to capture real-time perception while limiting post hoc rationalization or recall bias [24-26]. However, it remains unclear how clinicians’ real-time perceptions of crowding correspond to established objective crowding measures when both are assessed concurrently at high temporal resolution.

Hypothesis, Aims, and Objectives

To address this knowledge gap, we used a smartwatch-based EMA system to collect real-time EDPC data during clinical shifts. The primary aim of this study was to evaluate the concurrent associations between hourly median EDPC and the

XSL•FO
RenderX

corresponding hourly median values of the established objective crowding metrics: EDOR, NEDOCS, and EDWIN. Secondary analyses examined temporal associations between EDPC and these objective metrics. We also assessed interrater agreement among clinicians as a measurement property of EDPC and described response completion rates to characterize the feasibility of smartwatch-based EMA data collection.

Methods

Study Design

This prospective observational study combined retrospectively extracted electronic health record (EHR) data, used to derive the objective metrics, with prospectively collected clinician-reported crowding measures.

Setting

We recruited clinicians and obtained informed consent from November 12 to November 28, 2024. Data were collected in the ED of Samsung Medical Center, a tertiary referral hospital in Seoul, South Korea, from November 25, 2024, at 7 AM to December 13, 2024, at 11:59 PM, comprising 449 hourly observation time points. The study site has 1766 inpatient beds, including 67 ED beds, and manages approximately 65,000-70,000 ED visits annually. During the study period, ED operations were affected by a national medical workforce shortage following the mass resignation of residents and fellows [27,28]. Consequently, attending physicians delivered all ED care without junior medical staff, and the department operated 40 beds rather than its usual 67.

Participants

Inclusion and Exclusion

Eligible participants were attending physicians and charge nurses providing clinical care in the ED (central or acute care areas) during the study period; residents and fellows were not eligible because they were not involved in ED care at that time.

Sampling Procedures

We identified eligible clinicians from the duty roster, informed them about the study, and recruited them by voluntary nonprobability sampling; those who declined were not approached further, and written informed consent was obtained from all enrolled participants.

Of the 37 eligible clinicians, 28 (75.7%) participated, including 5 (35.7%) of 14 attending physicians and all 23 (100%) charge nurses; the remaining 9 attending physicians did not participate. Accordingly, the enrolled clinicians were not intended to constitute a representative sample of ED staff.

The observation period extended continuously from November 25, 2024, at 7 AM through December 13, 2024, at 11:59 PM, yielding 449 consecutive hourly assessment time points: 17 time points from 7 AM to 11 PM on November 25 and 24 time points per day for the subsequent 18 days. Rather than imposing artificial rater quotas or subsampling responses, we collected all responses from participating clinicians on duty. Based on the department's staffing model, each shift was staffed by at most 2 charge nurses and 1 to 3 attending physicians. Because duty periods could overlap across successive shifts, up to 3 charge nurses could be concurrently on duty during some hourly assessment periods. Because enrollment was voluntary, the number of participating clinicians on duty simultaneously varied across hourly assessment periods. Individual ratings within each hourly interval were aggregated into an hourly median EDPC value.

Participant Characteristics

Clinician demographic characteristics (age, sex, and years of clinical experience) and characteristics of ED patient visits during the study period (age, sex, triage acuity, and disposition) are reported in the Results section (Participant and Patient Characteristics).

Sample Size, Power, and Precision

No a priori sample size calculation was performed. The study size was determined by the prespecified data collection period and the number of eligible clinicians who volunteered. A total of 28 clinicians (5 physicians and 23 nurses) were enrolled, and 1100 individual EDPC ratings were obtained across 449 hourly observation time points. The precision of the estimated associations was assessed using 95% CIs. Because consecutive hourly observations were serially correlated, the 449 hourly time points were not considered statistically independent.

Assessments

Measures and Covariates

The primary outcome was EDPC, representing clinicians' perceived level of ED crowding. A raw EDPC entry was defined as a single clinician-reported rating recorded during an hourly assessment period. We then computed an hourly EDPC value by taking the median of all available entries within each hour. We chose the median value as the main hourly summary to provide a consistent measure of central tendency across hours with varying numbers of raters and to limit the influence of extreme ratings in hours with 3 or more raters. We defined the EDPC categories by anchoring scores to the 6 established NEDOCS severity categories (Not Busy, Busy, Extremely Busy, Overcrowded, Severely Overcrowded, and Dangerously Overcrowded) [17]. As the EDPC was recorded on a 0-200 numeric scale, this categorization followed the same point-based thresholds as the NEDOCS framework. This anchoring allowed direct comparison of clinicians' subjective perceptions with the objective operational thresholds defined by that framework.

The objective metrics EDOR, NEDOCS, and EDWIN [16-18] were calculated at a 1-minute temporal resolution using their respective published formulas implemented directly in R and evaluated as predictors of EDPC. These metrics represent different dimensions of ED crowding. Detailed formulas and variable definitions for all metrics are provided in Multimedia Appendix 1. Physician staffing data for the EDWIN calculation were taken from the duty roster and treated as time-varying. Physician shifts were scheduled as follows: *day* (D), 7:30 AM to 8:30 PM with 2 physicians; *evening* (E), 12 noon to 10 PM with 1 physician; and *night* (N), 8:30 PM to 7:30 AM with 2 physicians. When summarized by hourly assessment periods, under the usual staffing pattern, 2 physicians were on duty from

XSL•FO
RenderX

8 AM to 11:59 AM, 3 from 12 noon to 9:59 PM, and 2 from 10 PM to 7:59 AM the following morning. The only exceptions occurred during the N shifts beginning on November 26 and 27, 2024, when 1 physician rather than 2 was assigned to the N shift. We calculated EDWIN using the actual number of physicians scheduled on duty at each time point according to the duty roster, including these exceptions. We aggregated the objective crowding metrics into hourly summary statistics (mean, median, minimum, and maximum) for direct comparison with the hourly EDPC data.

To characterize the study population, we extracted demographic and clinical variables for each visit, including age, sex, acuity level according to the Korean Triage and Acuity Scale (KTAS), vital signs, and clinical disposition (categorized as discharge, hospital admission, transfer, death, or leaving without being seen). The latter category comprised patients who completed triage but left before entering the ED treatment area or being seen, either returning home or seeking care at another hospital. Because they remained in the ED census while physically present after triage, they contributed to the objective crowding metrics during that period.

Instrumentation

Raw EDPC entries were collected using a smartwatch-based system designed to support EMA [24-26] and to enable real-time assessment of clinicians' perceptions during active clinical shifts. Assessing perceptions in the moment was intended to reduce the recall bias associated with retrospective assessment. The research team developed a custom smartwatch application to support repeated real-time assessment within the clinical workflow. The 0-200 NEDOCS scale and its 6 crowding categories were adopted as reference anchors, giving clinicians an intuitive and standardized framework for rating their perceived crowding.

Four study smartwatches (Galaxy Watch 4 Classic; Samsung Electronics) running the custom application described above were provided for EDPC assessments. Participating clinicians wore the study smartwatches only during their on-duty shifts, and the devices were shared across successive shifts rather than assigned to individual participants. Participants did not use their personal smartwatches.

No formal pilot-testing of the EDPC instrument was conducted before the study.

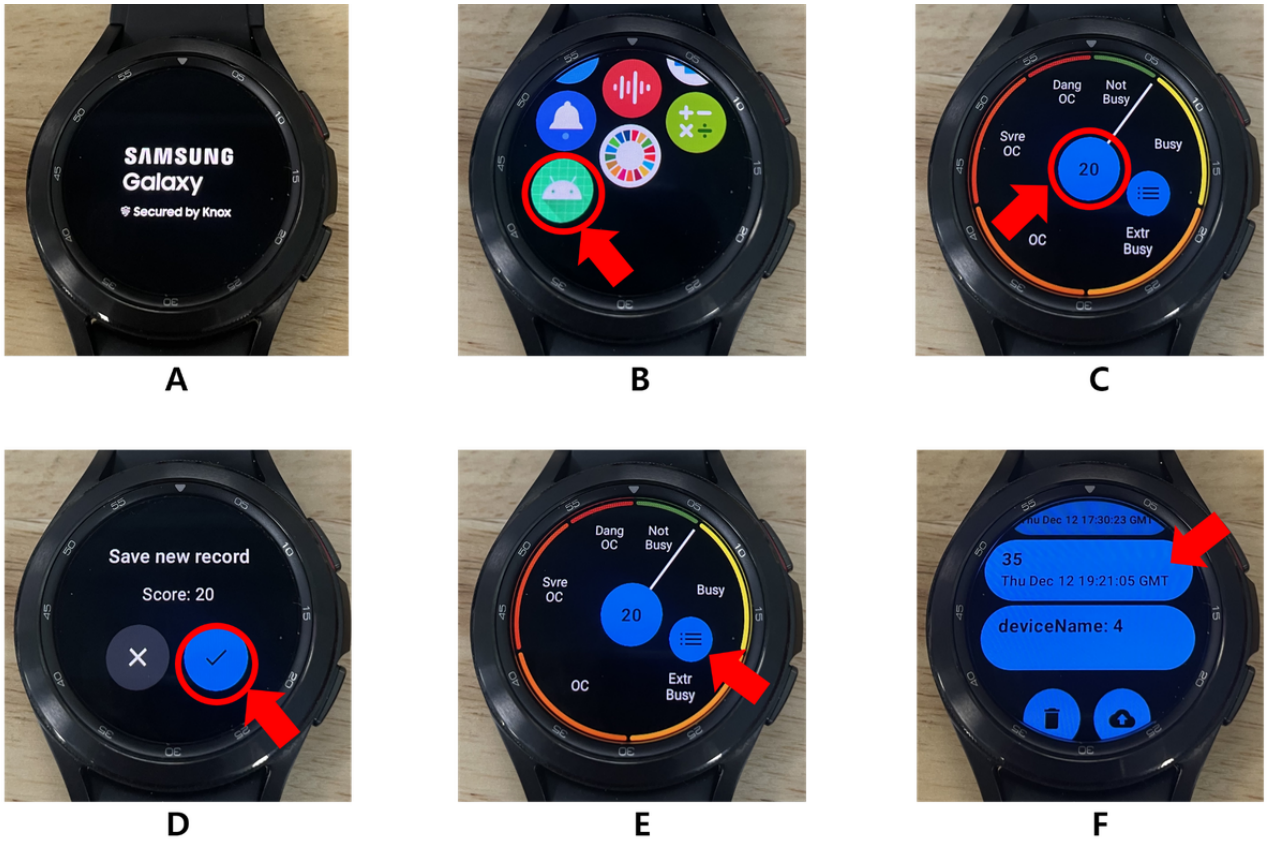
Quality of Measurements

Before data collection, participants received a brief orientation on using the smartwatch application and the EDPC assessment procedure. We demonstrated the interface, including how to launch the application, enter a rating, and modify one already entered. Participants were informed that the interface displayed the 6 crowding categories based on the NEDOCS framework, with corresponding color-coded score ranges, and were instructed to use these references to rate perceived crowding once each hour.

Psychometrics

The interrater reliability of the raw EDPC entries was assessed using the Gwet weighted agreement coefficient (AC2) with ordinal weighting [29] at 447 hourly time points with at least 2 observed ratings. All available clinician ratings at each time point were included. We selected this approach because the number and composition of raters varied across hourly assessments. AC2 estimates with 95% CIs were calculated using the *irrCAC* package in R. As a complementary analysis of the continuous EDPC ratings, we fitted a crossed random-effects variance-component model with hourly time point and clinician as random intercepts to account for the changing and unbalanced rater composition.

Masking



Although the NEDOCS-based categories and score ranges were displayed as reference anchors, participants could not view the actual real-time NEDOCS score while recording EDPC. Participants also had no access to an ED occupancy dashboard or to calculated operational crowding scores, including EDOR and EDWIN.

Data Collection

We prospectively collected EDPC data from enrolled clinicians using the smartwatch-based EMA system. EDPC assessments were conducted hourly. To reduce missed entries, the application delivered a gentle vibration reminder at 30 minutes past each hour. Participants entered their EDPC ratings using the bezel-controlled smartwatch interface shown in Figure 1, with score selection performed using either the rotating bezel or direct touchscreen interaction, followed by touch-based confirmation. Participants could enter one EDPC rating during each hourly assessment period and could correct an erroneous entry within the same period. Each EDPC response was assigned to the clock hour in which it was recorded, regardless of the timing of the reminder (eg, a response recorded at 11:50 AM was assigned to the 11-11:59 AM hourly period). Entries were not mandatory; therefore, clinicians could skip them during urgent clinical situations. If no response was recorded during an hourly assessment period while a clinician was on duty, that assessment opportunity was considered missing. Off-duty periods were excluded from EDPC assessment opportunities. Prompt-level completion rates were calculated as the number of completed EDPC ratings divided by the number of assessment opportunities during clinicians' on-duty periods. These rates were summarized overall, by professional role, and by individual clinician.

XSL•FO
RenderX

Figure 1. Workflow and user interface of the smartwatch-based application for recording raw emergency department perceived crowding (EDPC) entries (Galaxy Watch 4 Classic). (A) Initial smartwatch home screen. (B) Launch of the EDPC application. (C) Main EDPC input interface where clinicians selected their perceived crowding level on a 0-200 scale using either the rotating bezel or direct touchscreen interaction, with the 6 National Emergency Department Overcrowding Score (NEDOCS) crowding category labels, corresponding score ranges, and color coding displayed as visual references. The abbreviated labels displayed on the smartwatch were Extr Busy (extremely busy but not overcrowded), OC (overcrowded), Svre OC (severely overcrowded), and Dang OC (dangerously overcrowded). (D) Touch-based confirmation screen for saving the selected EDPC score. (E) Option to modify or reenter a previously recorded score. (F) Stored EDPC entry with the corresponding time stamp. The interface reproduced the NEDOCS-based category labels, score thresholds, and corresponding color coding as visual reference anchors; the actual calculated NEDOCS score at the time of assessment was not displayed. The use of these NEDOCS-based visual anchors may have introduced anchoring bias in the clinicians' EDPC ratings.

To compare the EDPC with the validated objective metrics, we extracted retrospective patient-level data for all ED visits during the study period from Samsung Medical Center's Clinical Data Warehouse (DARWIN-C). To ensure the accuracy of crowding assessment, we excluded visits that did not contribute to operational crowding: (1) cases immediately transferred to independent care units (eg, pediatric zones or delivery rooms), (2) visits that did not use ED clinical resources (eg, dead-on-arrival cases or nonclinical visits), and (3) erroneous records identified during data validation. ED and hospital bed capacities used in the calculations were obtained from institutional operational records.

Data Analysis

Data Diagnostics

Missing EDPC ratings were assessed at the individual clinician-rating level. The Little missing completely at random (MCAR) test evaluated whether missingness was completely at random.

As a sensitivity analysis, multiple imputation (MI) was performed for missing EDPC ratings using predictive mean matching to generate 50 imputed datasets. The imputation model included clinician ID, hourly median EDOR, NEDOCS, and EDWIN, sine and cosine terms for time of day, and study day. Although clinician ID and temporal covariates were included as predictors, within-clinician and serial correlation structures were not explicitly modeled. Hourly median EDPC values were recalculated for each imputed dataset, and Pearson correlation coefficients were pooled using Rubin's rules after Fisher *z* transformation.

Analytic Strategy

Clinician characteristics and key study variables are summarized using descriptive statistics. Categorical variables are presented as frequencies and percentages, and continuous variables as means (SD) or medians (IQR), as appropriate.

We performed exploratory descriptive analyses of hourly EDPC and the objective metrics to examine their distribution and diurnal patterns over the study period. We then assessed the association between hourly EDPC and each objective metric at contemporaneous time points.

The main analyses examined contemporaneous Pearson correlations between hourly median EDPC and the hourly median values of EDOR, NEDOCS, and EDWIN; no single

XSL•FO
RenderX

correlation was prespecified as the primary comparison. Exploratory analyses additionally examined Pearson correlations between hourly median EDPC and the minimum, maximum, and mean hourly values of each objective metric. Correlation strength was interpreted according to Cohen conventional benchmarks as weak (<0.3), moderate (0.3-0.5), or strong (≥0.5) [30].

In addition, we analyzed individual clinician-level EDPC ratings with linear mixed-effects models to account for the multilevel structure of the data. In the overall analysis, clinician and hourly time point were included as random intercepts to account for repeated ratings within clinicians and clustering of ratings obtained at the same time point. Profession-stratified analyses were performed separately for nurses and physicians, with clinician included as a random intercept to allow for repeated ratings within individuals.

As a post hoc sensitivity analysis, we calculated Spearman rank correlations using the same hourly summary statistics as in the Pearson analyses, to assess the robustness of the main results to departures from linearity and distributional assumptions. For the median-to-median associations, Spearman rank correlations and scatterplots were also examined overall and separately for physicians and nurses, with least absolute deviations (LAD) regression lines used to visually characterize these associations.

To account for temporal dependence, additional sensitivity analyses used generalized least squares (GLS) regression with first-order autoregressive—AR(1)—errors; sine and cosine terms for time of day simultaneously adjusted for common 24-hour diurnal patterns. Residual autocorrelation was assessed using the Ljung-Box test. In addition, we obtained percentile-based 95% CIs for the original Pearson correlation coefficients from a calendar-day block bootstrap with 10,000 resamples, resampling entire study days with replacement so that within-day temporal dependence was preserved.

As an exploratory analysis, we performed time-lagged correlation analyses by shifting each objective metric relative to hourly EDPC within a lag window of ±2 hours. A positive lag indicated that the objective metric preceded EDPC (eg, lag +1 h compared EDPC at time t with the objective metric measured at time t–1 h), whereas a negative lag indicated that the objective metric followed EDPC (eg, lag –1 h compared EDPC at time t with the objective metric measured at time t+1 h). Lag 0 represented contemporaneous measurements. This window was selected to align with the hourly sampling frequency and to capture short-term associations while avoiding more distant relationships that are less likely to be meaningful. No adjustment for multiple comparisons was applied.

The significance level for all statistical tests was set at α=.05. Analyses were performed using R (version 4.3.2; R Foundation for Statistical Computing) [31].

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and was approved by the institutional review board (IRB) of Samsung Medical Center. Prospective collection of EDPC data from clinicians was approved under IRB number 2024-02-102, and written informed consent was obtained from all participating physicians and nurses before enrollment. Retrospective extraction of operational and clinical data from the hospital's Clinical Data Warehouse was approved under IRB number 2025-02-012, with a waiver of informed consent for the use of deidentified records. Clinician smartwatch responses and clinical data were deidentified using unique study identifiers and stored on encrypted, password-protected institutional servers to protect privacy and confidentiality. Participating clinicians were compensated KRW 3000 (US $2.10) per hour of participation. Compensation was calculated based on each clinician's total working hours during the study period. The mean participation time was 40.5 hours per clinician, corresponding to a mean compensation of approximately KRW 121,393 (US $84.96). The total compensation for all 28 participants was KRW 3,399,000 (US $2379). No identifying information about clinicians or patients is presented in the manuscript figures, user interface images, or supplementary materials.

Results

Participant Flow

Among 37 eligible clinicians, 28 (75.7%) participated in the study, including 5 (35.7%) of 14 eligible attending physicians and all 23 (100%) eligible charge nurses. Across the 449 continuous hourly observation intervals (November 25, 2024, 7 AM to December 13, 2024, 11:59 PM), clinicians completed 1100 of 1124 scheduled on-duty EDPC assessments, yielding an overall response rate of 97.86% and a missed-assessment rate of 2.14%. The completion rate was 99.45% (897/902) among nurses and 91.44% (203/222) among physicians (Table 1). The 24 missed assessments were concentrated in 7 of the 28 participants (range 1-15 missed prompts; Table S1 in Multimedia Appendix 1). Little test rejected the assumption that these data were MCAR (χ^2_3=12.3; *P*=.006). In the MI sensitivity analysis, the pooled correlations were similar to the observed-data estimates for EDOR (*r*=0.538, 95% CI 0.468-0.602; *P*<.001), NEDOCS (*r*=0.480, 95% CI 0.405-0.549; *P*<.001), and EDWIN (*r*=0.063, 95% CI –0.030 to 0.155; *P*=.19; Table S2 in Multimedia Appendix 1).

Age (years), mean (SD)	42.0 (6.7)	35.1 (5.0)	36.3 (5.9)
Sex, n (%)			
Female	3 (60.0)	18 (78.3)	21 (75.0)
Male	2 (40.0)	5 (21.7)	7 (25.0)
Total clinical experience (years), mean (SD)	16.2 (7.0)	10.8 (4.4)	11.8 (5.3)
EDPC assessment compliance			
Scheduled on-duty opportunities, n	222	902	1124
Completed EDPC ratings, n (%)	203 (91.44)	897 (99.45)	1100 (97.86)
Missed assessments, n (%)	19 (8.56)	5 (0.55)	24 (2.14)

[a]Clinical experience represents total years of practice rather than emergency department–specific experience. Participating physicians were attending physicians providing clinical care in the emergency department, and participating nurses were charge nurses assigned to the central or acute care areas.

Across all 449 scheduled hours, the median number of clinicians contributing ratings per hour was 2 (IQR 2-3; range 1-4). Specifically, 2 (0.4%) hours had 1 rater, 255 (56.8%) hours had 2 raters, 180 (40.1%) hours had 3 raters, and 12 hours (2.7%) had 4 raters. Hourly EDPC values were calculated as the median of all available clinician ratings within each time point, resulting in 449 aggregated EDPC observations. All 449 hourly time points had complete corresponding objective metric data and were retained for the association analyses. The 447 hourly time points with ratings from at least 2 clinicians were included in the interrater reliability analysis. The remaining 2 time points, each with only 1 clinician rating, were not eligible for that analysis but were retained for the association analyses.

During the study period, 1848 adult ED visits met the eligibility criteria. Two visits were excluded because both KTAS and vital sign data were missing, resulting in a final analytic sample of 1846 ED visits (Figure 2). “Visits without treatment” referred to visits in which patients did not undergo standard ED evaluation and consequently were not assigned a KTAS level. These included medication-only visits without further evaluation (n=2) and visits with no diagnostic evaluation (n=11). This group was distinct from patients categorized as “Left without being seen,” who completed triage but left before entering the ED treatment area or receiving treatment. Because visits without treatment were neither triaged nor included in the ED census, they were excluded from the study population and did not contribute to the objective crowding metrics.

Figure 2. Flow diagram of emergency department (ED) visits included in the study. This prospective observational study was conducted at a tertiary ED in Seoul, South Korea, from November 25 to December 13, 2024. The diagram shows ED visits assessed for eligibility, exclusions and their reasons, and the final analytic sample.

Recruitment

In total, 28 clinicians participated in this study, including 5 (17.9%) physicians and 23 (82.1%) nurses (Table 1).

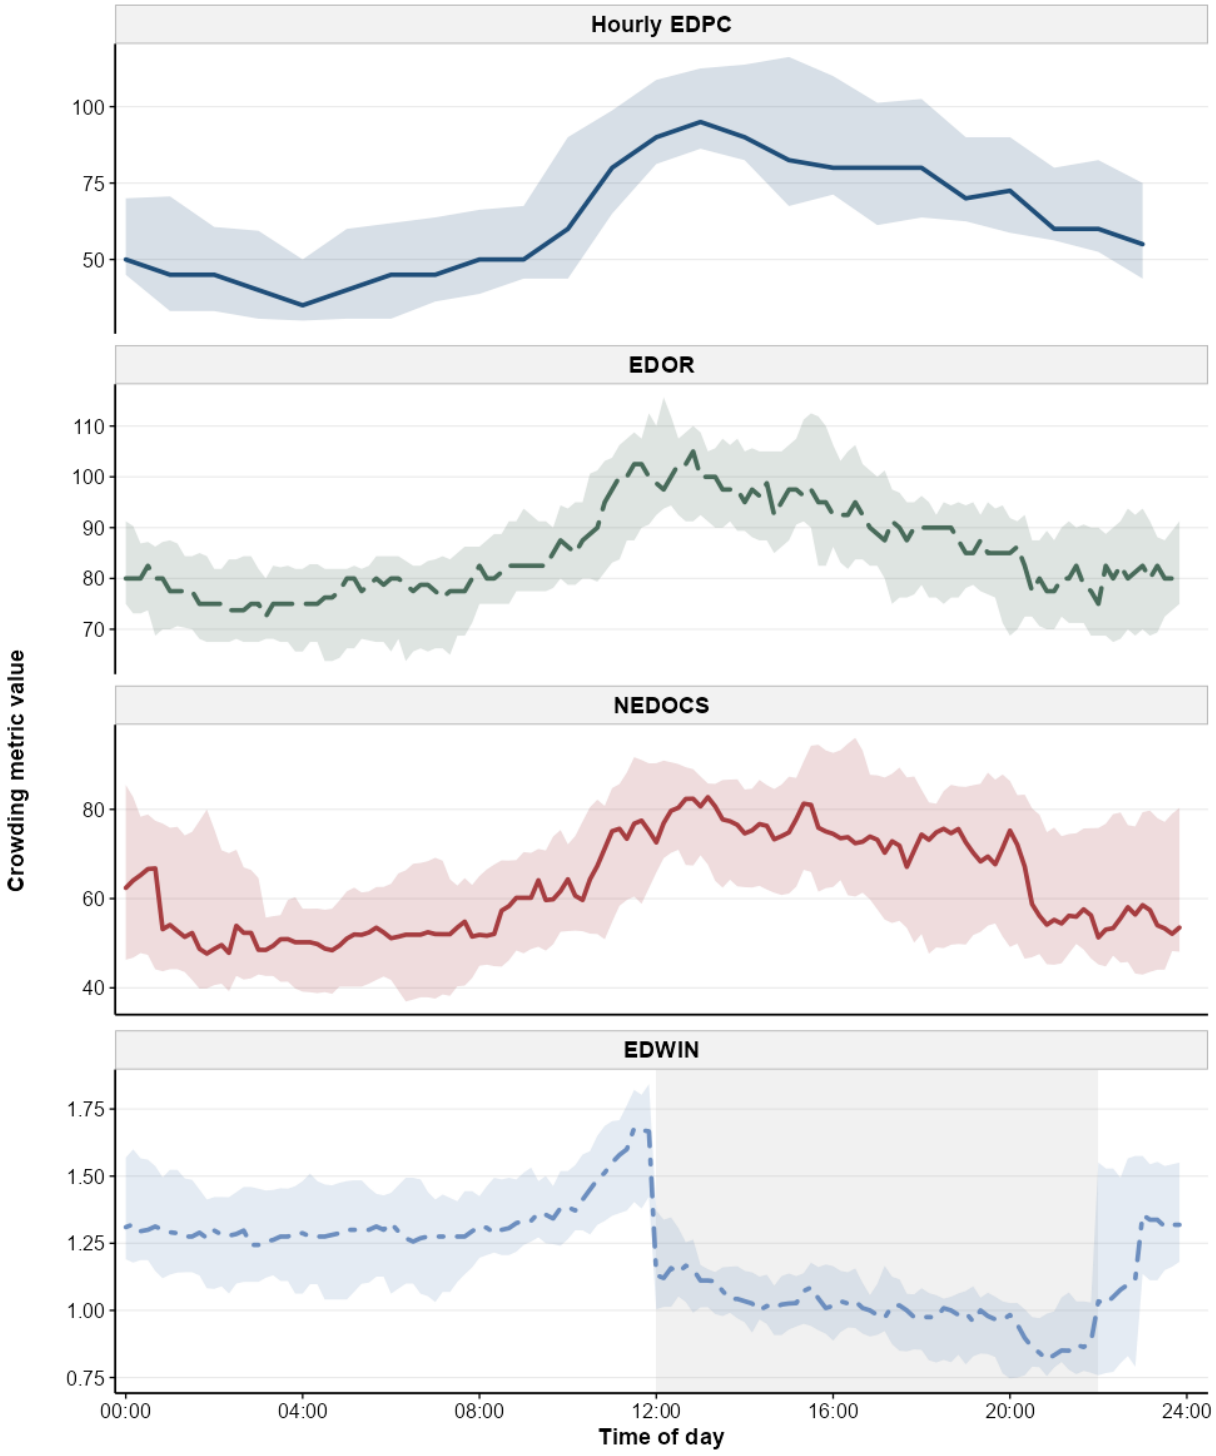
Statistics and Data Analysis

Participant and Patient Characteristics

The mean age of the participating clinicians was 36.3 (SD 5.9) years, with a mean clinical experience of 11.8 (SD 5.3) years. Clinical experience varied by professional role, with an average of 16.2 (SD 7.0) years for physicians and 10.8 (SD 4.4) years for nurses. Overall, 75% (21/28) of the participants were women.

The mean patient age was 57.7 (SD 20.4) years, and 52.1% (961/1846) of visits involved male patients. KTAS level 3 was the most common acuity category (1070/1846, 58%), followed by levels 4 (397/1846, 21.5%) and 2 (311/1846, 16.8%). Most patients were alert upon arrival (1785/1846, 96.7%). Regarding disposition, 31.9% (589/1846) of visits resulted in discharge, 25.2% (466/1846) in hospital admission, and 38.8% (717/1846) in leaving without being seen. Patient characteristics and outcomes varied substantially across KTAS levels. KTAS 1-2 visits involved older and more clinically unstable patients, with high admission rates (43.5%-47.6%) and a mortality rate of 39.1% (9/23) among KTAS 1 visits. In contrast, KTAS 4-5 visits involved younger patients and substantially higher rates of leaving without being seen (71.3%-91.1%; Table S3 in Multimedia Appendix 1).

Reliability of EDPC Measurements



Overall and profession-specific EDPC assessment completion rates are presented in Table 1, and individual clinician-level assessment completion data are provided in Table S1 in Multimedia Appendix 1. EDPC ratings from at least 2 clinicians were available at 447 (99.6%) of the 449 hourly time points. Interrater reliability analysis demonstrated substantial agreement for raw EDPC scores (AC2=0.742, 95% CI 0.712-0.772) and almost perfect agreement after conversion to NEDOCS categories (AC2=0.811, 95% CI 0.790-0.833). In the complementary variance-component analysis of continuous EDPC ratings, 25.2% of the total variance was attributable to hourly time points, 23.5% to between-clinician differences, and 51.3% to residual variation.

Diurnal Patterns of Hourly EDPC and Objective ED Crowding Metrics

The distributions of hourly median EDPC and the hourly median values of EDOR, NEDOCS, and EDWIN are summarized in Table S4 in Multimedia Appendix 1. Both the perceived and objective crowding measures showed clear diurnal variation (Figure 3). The hourly EDPC across all raters increased after 7 AM, peaked at 1 PM, and gradually declined thereafter. Temporal patterns varied by professional role: nurse-reported hourly EDPC peaked at 1 PM, whereas physician-reported hourly EDPC remained elevated between 2 and 4 PM (Figure S1 in Multimedia Appendix 1). These role-specific patterns are presented descriptively and should be interpreted cautiously given the small number of participating physicians.

XSL•FO
RenderX

Figure 3. Diurnal patterns of hourly emergency department perceived crowding (EDPC) and objective emergency department crowding metrics. Data were collected at a tertiary ED in Seoul, South Korea, from November 25 to December 13, 2024. Lines represent median values calculated from observations pooled within each 10-minute time-of-day bin across the study period. Shaded bands represent the IQR (25th-75th percentile) of day-specific median values within each corresponding bin, indicating day-to-day variability. In the Emergency Department Work Index (EDWIN) panel, the vertical gray band marks the period when 3 physicians were usually on duty (12:00-21:59), and the unbanded areas mark the periods when 2 were (08:00-11:59 and 22:00-07:59 the following day). EDOR: emergency department occupancy rate; NEDOCS: National Emergency Department Overcrowding Score; EDWIN: Emergency Department Work Index.

Objective indices showed overall diurnal patterns similar to those of hourly EDPC, but with distinct features across metrics (Figure 3). NEDOCS showed 2 local peaks at approximately 1 and 3:30 PM. EDOR showed a late-morning peak at approximately 11:30 PM, followed by a generally declining pattern with some variability. EDWIN, in contrast, followed a different profile: a primary peak in the late morning (approximately 11:30 PM), then a rapid drop and a secondary peak in the late evening (approximately 11:20 PM).

XSL•FO
RenderX

Associations Between EDPC and Objective ED Crowding Metrics

Table 2 shows correlations between hourly EDPC and summary statistics of the 3 objective metrics. All Pearson correlation analyses were based on 449 paired hourly observations. EDPC correlated strongly with EDOR (r=0.53-0.56) and moderately to strongly with NEDOCS (r=0.47-0.51), whereas EDWIN showed no significant correlation.

Table 2. Pearson correlation between hourly emergency department perceived crowding and hourly summary statistics of objective metrics[a].

	Pearson *r* (95% CI)	*P* value
EDOR[b]		
Minimum	0.527 (0.457 to 0.591)	<.001
Maximum	0.563 (0.496 to 0.623)	<.001
Mean	0.545 (0.477 to 0.607)	<.001
Median	0.542 (0.473 to 0.604)	<.001
NEDOCS[c]		
Minimum	0.473 (0.398 to 0.542)	<.001
Maximum	0.510 (0.439 to 0.576)	<.001
Mean	0.492 (0.419 to 0.559)	<.001
Median	0.483 (0.409 to 0.551)	<.001
EDWIN[d]		
Minimum	0.014 (–0.079 to 0.106)	.77
Maximum	0.090 (–0.003 to 0.181)	.06
Mean	0.052 (–0.041 to 0.144)	.27
Median	0.060 (–0.033 to 0.152)	.20

[a]Each Pearson correlation analysis was based on 449 paired hourly observations.

[b]EDOR: emergency department occupancy ratio.

[c]NEDOCS: National Emergency Department Overcrowding Score.

[d]EDWIN: Emergency Department Work Index.

Post hoc sensitivity analyses using Spearman rank correlations yielded results consistent with the Pearson analyses. EDPC showed significant positive rank correlations with all summary statistics of EDOR (ρ=0.53-0.57; all P<.001) and NEDOCS (ρ=0.47-0.52; all P<.001), whereas EDWIN showed no significant correlations (ρ=–0.02 to 0.08; P=.09-.63; Table S5 in Multimedia Appendix 1). Scatterplots of hourly median EDPC against the hourly median EDOR, NEDOCS, and EDWIN values, with LAD regression lines and Spearman correlation coefficients, are presented overall and separately for physicians and nurses (Figure S2 in Multimedia Appendix 1).

In clinician-level multilevel analyses using all 1100 individual EDPC ratings and accounting for clustering by both clinician and hourly time point, EDPC was significantly associated with median EDOR (β=.966, 95% CI 0.840-1.091; P<.001) and median NEDOCS (β=.651, 95% CI 0.558-0.745; P<.001), but not with median EDWIN (β=3.865, 95% CI –1.761 to 9.490; P=.18; Table 3). Profession-stratified analyses showed the same pattern of statistical significance in nurses and physicians, with EDOR and NEDOCS significantly associated with EDPC and EDWIN showing no significant association in either professional group. The estimated EDWIN coefficient was positive for nurses (β=4.114) and negative for physicians (β=–.825), although neither association was statistically significant (Table 3).

Additional temporal sensitivity analyses showed that EDOR and NEDOCS remained significantly associated with hourly EDPC after simultaneously accounting for serial correlation and common time-of-day patterns using GLS AR(1) models (both P<.001). EDWIN was also significantly associated with EDPC after adjustment for both temporal components (P=.004; Table S6-A in Multimedia Appendix 1). Calendar-day block bootstrap analyses of the original Pearson correlations yielded 95% CIs excluding zero for EDOR (r=0.542, 95% CI 0.417-0.661) and NEDOCS (r=0.483, 95% CI 0.389-0.581), but not for EDWIN (r=0.060, 95% CI –0.165 to 0.234; Table S6-B in Multimedia Appendix 1).

In exploratory time-lagged correlation analyses, EDOR consistently showed positive correlations with EDPC across the ±2-hour lag window. NEDOCS followed a similar pattern, whereas EDWIN generally showed weaker associations across the lag conditions. The temporal patterns are presented in Figure S3 in Multimedia Appendix 1, and complete results, including lag direction, number of paired observations, correlation coefficients, 95% CIs, and unadjusted P values, are provided in Table S7 in Multimedia Appendix 1. P values were not adjusted for multiple comparisons because these analyses were exploratory.

XSL•FO
RenderX

Table 3. Multilevel analyses of associations between individual clinician-level emergency department perceived crowding ratings and objective emergency department crowding metrics.

Objective metric	Ratings, n	Clinicians, n	Hourly time points, n	β (95% CI)	SE	*P* value
Overall multilevel analysis[a]						
EDOR[b]	1100	28	449	.966 (0.840 to 1.091)	0.064	<.001
NEDOCS[c]	1100	28	449	.651 (0.558 to 0.745)	0.048	<.001
EDWIN[d]	1100	28	449	3.865 (–1.761 to 9.490)	2.870	.18
Profession-stratified multilevel analysis[e]						
Nurse						
EDOR	897	23	449	.985 (0.853 to 1.116)	0.067	<.001
NEDOCS	897	23	449	.641 (0.545 to 0.738)	0.049	<.001
EDWIN	897	23	449	4.114 (–1.389 to 9.616)	2.807	.14
Physician						
EDOR	203	5	191	.810 (0.620 to 1.000)	0.097	<.001
NEDOCS	203	5	191	.693 (0.549 to 0.838)	0.074	<.001
EDWIN	203	5	191	–.825 (–8.251 to 6.602)	3.789	.83

[a]Linear mixed-effects models were fitted using individual clinician-level emergency department perceived crowding ratings as the outcome and the median value of each objective crowding metric at the corresponding hourly time point as the predictor. Overall models included random intercepts for both clinician and hourly time point to account for repeated ratings within clinicians and clustering within the same time point. β represents the unstandardized regression coefficient.

[b]EDOR: emergency department occupancy ratio.

[c]NEDOCS: National Emergency Department Overcrowding Score.

[d]EDWIN: Emergency Department Work Index.

[e]Profession-stratified linear mixed-effects models included clinician as a random intercept to account for repeated ratings within clinicians. A separate hourly time point random intercept was not retained in the stratified models because within-hour replication was sparse in the physician subgroup. β represents the unstandardized regression coefficient.

Discussion

Support of Original Hypotheses (Primary Findings)

Clinician-perceived crowding, measured as the hourly EDPC, was associated with established objective crowding measures, although the magnitude and consistency of these associations differed across metrics. EDPC showed consistent associations with EDOR and NEDOCS, whereas its association with EDWIN depended on whether common time-of-day patterns were explicitly adjusted for. These findings suggest that clinician-perceived crowding may provide complementary information to objective crowding metrics. The high response rate supports the feasibility of repeated real-time EDPC assessment during routine clinical shifts.

Similarity of Results

Alignment of Hourly EDPC With Objective Crowding Measures

Hourly EDPC correlated moderately to strongly with occupancy-based measures, such as EDOR [15,16] and NEDOCS [17]. Clouston et al [12] demonstrated that ED occupancy, despite its simplicity, had a predictive accuracy similar to that of complex crowding scores such as NEDOCS and was useful for real-time tracking. Furthermore, recent before-and-after evidence indicates that transition units can reduce boarding and NEDOCS-defined crowding, illustrating that occupancy- and boarding-based measures may be particularly responsive to changes in hospital access block [32]. Our findings are consistent with this observation. Occupancy-based metrics may align well with EDPC because clinicians managing a growing number of patients directly experience the physical saturation of treatment spaces; however, this study cannot establish the specific mechanism underlying this association.

Hourly EDPC showed significant positive correlations with EDOR and NEDOCS across all 4 hourly summary statistics (minimum, maximum, mean, and median). Descriptively, correlations of EDPC with the maximum values of EDOR and NEDOCS were slightly higher than those with the corresponding mean or median values. However, these differences were small, and the dependent correlation coefficients were not formally compared; therefore, this observation should not be interpreted as evidence that clinician-perceived crowding is more strongly associated with peak values. Prior work has suggested that traditional crowding metrics may not fully capture the dynamic, rapidly fluctuating nature of ED operations [33], and that the relationship between objective crowding and clinician perception may be nonlinear [19]. These observations motivate further study of whether within-hour fluctuations or peak crowding conditions disproportionately shape clinician perceptions. Although we examined both median and peak crowding metrics,

XSL•FO
RenderX

this study cannot determine which measure best represents clinicians' subjective experience.

Comparison With Previous Real-Time Perception Studies

This study builds on the work of Boverio et al [19], who demonstrated the potential of real-time subjective assessments using EMA. Boverio et al [19] used smartphone text messages twice daily, a method limited by low measurement frequency and by the need to use a smartphone during clinical workflows, whereas our study used a smartwatch-based application with hourly prompts. Subtle wrist-vibration reminders prompted clinicians to complete hourly EDPC assessments through the application during routine clinical shifts. This approach was intended to reduce interruption and recall bias relative to retrospective, single–time point assessments, although these potential benefits were not directly measured and require further evaluation.

Patient-centered research further highlights discrepancies between objective measures and subjective perceptions of ED crowding. Wang et al [34] examined patient-perceived crowding at the end of ED encounters and observed variable agreement with objective indices. However, their study relied on a single–time point measurement, whereas our study captures clinicians' perceptions repeatedly throughout their clinical shifts, allowing for a more dynamic assessment.

Schippers et al [35] developed an AI-driven predictive model using routinely collected operational parameters to predict ED crowding, with ambulance diversion status as a binary outcome. In contrast, our study examines perceived crowding across varying levels of crowding through repeated, real-time assessments, rather than focusing on the threshold of ambulance diversion. Our findings demonstrate associations between objective crowding metrics and clinician-reported EDPC, suggesting that these metrics reflect certain aspects of clinicians' experiences of crowding but may not fully capture their subjective perceptions. Future qualitative research could explore discrepancies between operational indicators and clinicians' experiences in greater depth, providing insights into the contextual factors that shape perceived crowding beyond what quantitative measures can capture.

Interpretation

Interrater Agreement and Variability

Weighted AC2 indicated substantial ordinal agreement among clinicians' EDPC ratings (AC2=0.742). However, the complementary variance-component analysis showed that 25.2% of the total variance was attributable to hourly time points, 23.5% to between-clinician differences, and 51.3% to residual variation. These findings reflect different aspects of agreement and variability. Ordinally weighted AC2 allows partial agreement between nearby scores, whereas the variance-component analysis quantifies different sources of variability in the continuous ratings. Taken together, these findings suggest partial concordance in perceived crowding rather than interchangeability of individual clinician ratings.

Temporal Robustness and Interpretation of Associations

The associations of EDPC with EDOR and NEDOCS remained consistent across analyses accounting for serial correlation, common time-of-day patterns, and within-day temporal dependence, supporting their robustness to the temporal structure of the data. In contrast, the results for EDWIN were less consistent across the temporal sensitivity analyses. Although the original Pearson correlation and calendar-day block bootstrap analysis did not show a significant association between EDPC and EDWIN, a significant association emerged in models that explicitly adjusted for time-of-day patterns. These findings indicate that the EDPC-EDWIN association was sensitive to the adjustment for diurnal variation and should therefore be interpreted cautiously.

Occupancy-based metrics showed more consistent associations with hourly EDPC than EDWIN did. Notably, the diurnal profile of EDWIN diverged in shape from that of EDPC, EDOR, and NEDOCS: whereas the latter 3 measures peaked in the late morning to early afternoon, EDWIN exhibited an additional secondary peak in the late evening (approximately 11:20 PM) that was not mirrored by a corresponding rise in EDPC. This divergence in diurnal shape, rather than the shared presence of diurnal variation per se, may partly explain the inconsistency of the EDWIN-EDPC association across analytic approaches.

This finding must also be interpreted within the operational context of this study. Although EDWIN has the theoretical advantage of incorporating patient acuity [18], it also incorporates physician staffing, which varied over time during the study period. During a recent disruption in the physician workforce in South Korea [27], only 1 to 3 attending physicians delivered ED care, and the number of operational beds was reduced from 67 to 40. Therefore, the EDWIN findings should be interpreted in the context of this atypical staffing environment. Because EDWIN incorporates physician staffing and bed capacity directly into its formula [18], fluctuations in these structural components may influence the metric independently of clinicians' perceived crowding. This sensitivity analysis suggests that the inconsistent unadjusted association between EDWIN and EDPC in this study may be related to the exceptional staffing context and the staffing-sensitive construction of the metric; however, this study cannot establish that staffing variability was the sole or primary explanation. Considering that EDWIN aligned with staff assessments in its original development study and has been used in other settings [36], our findings should not be interpreted as evidence that EDWIN is not generally useful. Instead, staffing-sensitive metrics such as EDWIN should be applied with caution in smaller EDs and in those that adjust staffing in response to crowding.

In exploratory time-lagged analyses, EDPC showed similar correlations with objective crowding measures at lag 0 and at both +1-hour and –1-hour lags, indicating similar associations when the objective metrics preceded or followed EDPC by 1 hour. Because lagged correlations can arise from autocorrelation and shared diurnal trends rather than a genuine predictive relationship, and because predictive performance was not assessed, this finding should be interpreted as an exploratory

XSL•FO
RenderX

temporal association rather than evidence that EDPC functions as a leading indicator of crowding. Clinicians may detect early cues of worsening crowding, but confirmation of any predictive relationship would require dedicated time-series and prospective prediction analyses.

Role-Specific Differences in Perceived Crowding

Descriptively, nurse- and physician-reported EDPC showed different peak timing across the day (Figure S1 in Multimedia Appendix 1). However, in the profession-stratified multilevel analyses, EDOR and NEDOCS were significantly associated with individual EDPC ratings in both nurses and physicians, whereas EDWIN was not significantly associated with EDPC in either group. Thus, despite the descriptive differences in diurnal patterns, the pattern of associations with the objective crowding metrics was similar across professions. These findings should be interpreted cautiously given the small number of participating physicians (n=5) and require confirmation in larger, more balanced samples. Previous studies have shown that perceived crowding differs significantly across professional roles in the ED, including among nursing roles [19]. Because our study included only charge nurses and attending physicians, future research could incorporate other clinical roles, administrative staff, and patients to examine differences in perceived crowding across stakeholder groups and explore the factors underlying these differences.

Generalizability

The applicability of the assessment approach and the observed associations may vary across settings. Hourly smartwatch-based reporting could be adapted to other EDs, although the short study period limits conclusions about sustained participation and acceptability in routine practice. The magnitude and pattern of associations between EDPC and objective metrics may also vary according to staffing models, operational capacity, and patient populations. In particular, the attending-only staffing model and reduced bed capacity during the exceptional workforce disruption observed in this study may limit generalizability to EDs operating under routine conditions. Multicenter studies with longer observation periods under routine operating conditions are needed to evaluate sustained participation and the consistency of these associations across settings.

Implications

Clinical Importance of Clinician-Perceived Crowding

These findings have important implications for ED care delivery. Previous studies have consistently shown that ED crowding is associated with an increased length of stay, delays in care, reduced care quality, and poor patient safety outcomes [1,3]. Crowding arises when demand for services exceeds a department's available resources [4], and ED clinicians play a critical role in timely patient assessment [22,23], initiation of time-sensitive treatment [37], and recognition of clinical deterioration [38]. Prior literature has also characterized ED clinicians' workload as involving substantial cognitive demands and time pressure that are not fully captured by structural factors such as bed and patient numbers [39].

Objective metrics often assume static patient conditions, whereas the ED environment and patient status can change rapidly [40]. Real-time monitoring tools have been proposed to better capture these fluctuations [19,33]. In this context, hourly EDPC may provide complementary information about clinicians' real-time experience of crowding that is not captured by structural metrics alone; whether this information reflects cognitive load, safety risk, or other unmeasured dimensions of operational burden was not evaluated in this study and remains an open question for future research.

Methodological Contributions and Future Directions

The high overall response rate of 97.9% (1100 of 1124 expected on-duty assessments) supports the feasibility of this approach for frequent EDPC assessments during routine clinical shifts. This finding indicates that clinicians could complete hourly ratings consistently during the study period. However, acceptability, sustainability, and documentation burden were not directly measured relative to other assessment methods and require further evaluation. Documentation burden, the increased time and effort required to record care, is a well-known contributor to professional burnout syndrome [41,42]. Moreover, many health care technologies are abandoned when they introduce excessive complexity or demand substantial changes to established clinical routines [43]. Although the smartwatch interface was designed to minimize this burden through score selection using either the rotating bezel or direct touchscreen interaction, followed by touch-based confirmation, this study did not directly assess whether it achieved this relative to other data collection methods.

Importantly, the implementation did not require each participant to own or be assigned an individual smartwatch. Study devices were shared across successive shifts, so the number required depended on how many participating clinicians were concurrently on duty rather than on total enrollment. This device-sharing approach may reduce hardware requirements and remove the need for clinicians to own compatible devices. Nevertheless, the feasibility, cost, and scalability of this approach in larger or differently staffed EDs were not evaluated in this study and require further investigation.

Despite these methodological advantages, our approach did not entirely overcome the interruptive nature of active EMA. Raw EDPC entries may have been missed more frequently during periods when clinicians were too busy to record them [44]. In addition, as participation was voluntary, it remains uncertain whether this active recording approach is sustainable in routine practice outside the research setting.

Our findings do not imply that subjective perceptions should be used as stand-alone metrics for ED crowding. Relying solely on subjective assessments carries inherent clinical risk. As Garcia-Romero et al [20] have demonstrated, clinicians who are chronically exposed to excessive crowding tend to underestimate objectively measured crowding levels, a pattern consistent with the "normalization of deviance." To address both the interruptive limitations of EMA and individual clinicians' tendency to underestimate crowding, future research should focus on hybrid monitoring models. As a hypothesis-generating direction, future work could combine

XSL•FO
RenderX

active EDPC data with passive smartwatch-based physiological sensing (such as heart rate variability) [45], and objective EHR-based metrics in a multidimensional monitoring approach. Such an approach remains speculative at this stage; whether it could support applications such as early identification of rising operational burden or resource-reallocation alerts would require dedicated development and prospective validation before any clinical implementation could be considered.

Beyond technical feasibility, future research should use effectiveness-implementation hybrid designs to evaluate the acceptability, adoption, and long-term sustainability of smartwatch-based EDPC assessments. These studies could also investigate strategies to minimize reporting burden and protect frontline staff well-being. Furthermore, research should explore how real-time EDPC assessments could inform actionable thresholds for resource allocation and operational decision-making.

Limitations

This study had several limitations. First, it was conducted in a single tertiary hospital over a relatively short period, limiting its generalizability. Although EDPC and objective crowding metrics were measured at high temporal resolution, the limited study duration did not allow us to assess seasonal variation in ED crowding or in clinician perceptions.

Second, the EDPC instrument used NEDOCS-derived anchors, categories, and score ranges, and has not been independently validated against other subjective or objective crowding measures. Although participants could not view the actual real-time NEDOCS score while recording EDPC, the shared framework may have influenced clinicians' subjective ratings through anchoring or criterion contamination and contributed to the observed association between EDPC and NEDOCS. This design-related limitation cannot be resolved through statistical adjustment alone; accordingly, that association should not be interpreted as independent validation of either measure. Future validation studies should use neutral scale anchors that do not reproduce the categories or thresholds of the comparator metric.

Third, the study was conducted during an unprecedented national health care workforce crisis. During this study, attending physicians delivered all ED care, without residents or fellows, and as a crisis response, only 40 of the 67 ED beds were operational. This exceptional staffing and capacity context is not solely a threat to generalizability: because EDWIN incorporates physician staffing and bed capacity directly into its formula, these conditions may have altered the metric's internal behavior, complicating interpretation of its association with EDPC.

Fourth, to minimize disruption of routine clinical care, our study design permitted missed responses. Little MCAR test rejected the assumption that these responses were MCAR, indicating that missingness may have been systematically related to observed or unobserved factors. For example, clinicians may have been unable to record entries during periods of extreme workload or severe crowding. Although MI produced similar correlation estimates, the imputation model did not explicitly account for within-clinician or serial correlation, and missing-data bias remains possible. Additionally, participation in this study was voluntary, and it remains uncertain whether this active recording approach would be sustainable in routine, nonresearch clinical practice.

Fifth, multiple statistical comparisons were performed without adjustment for multiplicity, and no single primary comparison was prespecified. Therefore, the possibility of inflated type I error cannot be excluded, and the findings should be interpreted with caution.

Conclusion

This prospective observational study provides methodological and empirical insights into measuring ED crowding. Using dedicated smartwatch-based EMA, we captured clinicians' perceptions in situ at high temporal frequency during active shifts, potentially reducing susceptibility to retrospective recall bias while minimizing the spatial constraints of traditional survey methods. During an exceptional health care workforce disruption, hourly median EDPC was moderately associated with EDOR and NEDOCS, whereas its association with EDWIN was less consistent across temporal sensitivity analyses. These findings warrant further investigation of EDPC as a complementary measure of ED crowding alongside established objective metrics. However, our findings do not establish that EDPC directly measures cognitive workload or predicts subsequent crowding. The high response rate (1100/1124, 97.9%) supports the feasibility of wearable-based momentary assessments in acute care. Future studies should evaluate the generalizability of these findings across diverse ED settings and further assess the validity of EDPC as a complementary crowding measure using independently anchored scales, appropriate time-series analyses, and multicenter designs.

Acknowledgments

The authors would like to express their sincere gratitude to the emergency department clinicians who generously participated and contributed to this research.

Funding

This work was supported by a grant from the Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (grant number RS-2024-00335925). The funder had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Data Availability

Data supporting the findings of this study are available from the corresponding author upon request. These data are not publicly available due to institutional and ethical restrictions related to patient and clinician confidentiality.

Generative AI Use

During the preparation of this manuscript, the authors used ChatGPT (GPT-5.5/GPT-6; OpenAI) and Gemini (Gemini 1.5 Pro; Google). According to the Generative AI Delegation Taxonomy [46], the following tasks were delegated to generative AI tools under full human supervision: literature search and systematization, data cleaning, proofreading and editing, translation, and reformatting. All outputs produced with these tools were thoroughly reviewed, verified, and critically evaluated by the authors. Responsibility for the final manuscript lies entirely with the authors. These tools are not listed as authors and do not bear responsibility for the final outcomes.

Abstract

Background: Passive sensing for mobile mental health relies on observations that can differ across smartphone platforms. Distinguishing behavioral differences from differences in observation is necessary before using these features for symptom screening or monitoring.

Objective: We quantified platform-associated differences, feature availability, sensitivity to preprocessing, and the predictive contribution of connectivity features within the Generalization of Longitudinal Behavior Modeling (GLOBEM) dataset and its collection and processing pipeline.

Methods: We analyzed 4 annual US college cohorts from 2018 to 2021, comprising 705 annual records from 497 people reported by the dataset investigators. The feature sample contained 554 iOS and 151 Android records. Without verified cross-year identity links, inference and cross-validation were performed separately within each cohort. We compared 15 raw constructs and matched transformations using Cliff δ, participant resampling, and fixed logistic regression. Phone-derived location and screen features were separated from Fitbit activity and sleep measures. Analyses included coverage, complete cases, psychological adjustment, and retrospective depressive-symptom screening using the preceding 14 days.

Results: Total Bluetooth scan counts were lower on iOS in every cohort (Cliff δ −1.00 to −0.85). Connectivity counts differed more between platforms than core phone behavioral features did (difference in mean absolute Cliff δ 0.22-0.43; all 95% CIs above zero). Smaller observed-value differences did not imply equal coverage: 41 of 103 iOS records lacked all home-time values in 2020, compared with 0 of 34 Android records. Platform-classification area under the receiver operating characteristic curve (AUROC) was 0.94 to 0.997 for 13 raw constructs, 0.34 to 0.91 after normalization, and 0.65 to 0.80 after discretization. Bluetooth differences persisted after psychological adjustment. In 661 eligible screening windows, behavioral-model AUROC ranged from 0.41 to 0.56. All behavioral, connectivity-added, and platform-added models had worse Brier scores than the intercept-only benchmark. Adding connectivity changed AUROC by 0.004 to 0.034; every paired 95% CI included zero.

Conclusions: Within GLOBEM, selected connectivity features showed larger platform-associated differences than core phone behavioral features, while availability problems also affected location. Weak screening performance limits what these comparisons can establish about downstream harm. Platform-specific coverage and outcome calibration require assessment before interpreting sensing features as clinical markers.

Introduction

Measurement in Mobile Mental Health

A low smartphone-derived activity or communication value can reflect behavior, limited observation, or both. This ambiguity matters when mobile health (mHealth) apps use passive sensing to supplement depression screening or monitor changes between clinical assessments. Early research linked location and phone-use features to depressive symptoms [1]. Subsequent work used communication traces to model clinically assessed mood and anxiety symptoms [2], and screen and connectivity features to classify questionnaire-defined depression [3]. These studies motivate careful interpretation of the measurements supplied to a model, rather than treating a familiar feature name as evidence of comparable observation across devices.

Communication and proximity features are used as proxies for social engagement and withdrawal. Smartphone and Fitbit studies have related mobility, activity, and communication to loneliness [4]. Yet phone channels need not move together: Wang and colleagues [5] found fewer incoming contact calls but more frequent social-app use among Android users with depression-screen-positive scores. A call count is a recorded event count, and Bluetooth detections identify nearby devices rather than verified interpersonal contact. The distinction between a trace, a behavioral marker, and a clinical state is central to personal sensing models [6].

Monitoring an individual and ranking different individuals require different measurement evidence. Student studies have used repeated phone and wearable observations to model weekly symptoms and end-of-semester symptom changes [7,8]. A stable device-specific offset could affect between-person comparisons while preserving some within-person information. Intermittent observation or device replacement could affect both. Our annual platform comparisons address the former question; they do not evaluate personalized symptom trajectories.

Platform differences in observation are already documented. Halabi and colleagues [9] analyzed multimodal sensor data from approximately 3000 participants in real-world settings and found that data-quality features could identify Android versus iOS with accuracy as high as 0.98. The Reproducible Analysis Pipeline for Data Streams (RAPIDS), a toolkit for processing mobile sensing data, provides a common analysis framework, but its feature documentation describes platform-specific event handling [10]. Common output names therefore need not imply identical operational definitions. A systematic review of smartphone-only health sensing documented uneven operating-system coverage and incomplete platform reporting [11].

Prediction and measurement are distinct questions. Mobility-based depression prediction has performed differently across homogeneous student samples and heterogeneous populations [12]. The Generalization of Longitudinal Behavior Modeling (GLOBEM) benchmark also examined difficulties in generalizing longitudinal behavioral models across datasets [13]. Such findings do not identify platform as the cause. Conversely, high platform-classification performance establishes information about platform in a feature set, but does not establish that this information worsens a mental health model. Clinical relevance requires evaluation of the intended outcome and use case [14].

The GLOBEM benchmark restricted cross-dataset models to compatible feature classes and excluded Bluetooth, WiFi, and call features that were not common across its 2-institution datasets [13]. In its reimplementation of 2 earlier algorithms, most of the performance loss relative to the original studies was attributed to removing Bluetooth, WiFi, call, message, and battery features [13]. This practical loss of potentially informative communication and proximity measures motivates a feature-level comparability audit. That benchmark used 2 institutions across 2018 and 2019; the present analysis uses 4 annual cohorts from one institution and a different screening protocol.

Measurement Comparability and Predictive Use

Measurement comparability concerns observable events, feature definitions, and health inference. Goldsack and colleagues [15] distinguish technology verification, analytical validation, and clinical validation. Released features support an availability audit and outcome comparison, but simultaneous reference observations would be required to validate sensor accuracy or interchangeability.

Missingness may carry both technical and clinical information. Currey and Torous [16] found that coverage varied with app engagement and other factors in 1178 participants. In a small schizophrenia cohort, data-quality metrics were associated with symptom-related survey responses [17]. Comparing only observed means can therefore omit a relevant difference in the observation process.

Luijken and colleagues [18] showed analytically and through simulation that predictor-measurement differences between development and validation can affect performance. This establishes a possible pathway, not its presence in GLOBEM. We therefore evaluate platform recovery and symptom screening as separate tasks, with distinct outcomes and interpretations.

Between-person and within-person associations can differ. Yang and colleagues [19] separated app-use predictors into individual deviations and person averages and found different associations with loss of interest. Their Android study did not test cross-platform harmonization. It demonstrates why a classifier recovering platform from participant averages cannot establish whether deviations from an individual's baseline predict symptoms.

Objectives and Scope

We used 4 annual GLOBEM college cohorts to characterize platform-associated differences in released sensing features [20,21]. Our objectives were to locate these differences, distinguish phone-derived features from Fitbit measures, assess coverage and preprocessing, and evaluate whether adding selected connectivity features altered retrospective depressive-symptom screening. We use "platform-associated difference" for an observed contrast. We reserve "measurement artifact" for a documented incompatibility in collection or

XSL•FO
RenderX

feature meaning. We do not infer causal confounding, psychological independence, or measurement equivalence from platform classification alone.

We evaluated localization, contribution to platform prediction, sensitivity to transformation, and persistence after psychological adjustment. Coverage, matched-feature, and downstream analyses were exploratory extensions described in the "Methods" section. This secondary analysis was not preregistered and does not validate a clinical device.

Methods

Data Source and Analytical Units

The GLOBEM dataset, version 1.1, released as Multi-Year Datasets for Longitudinal Human Behavior Modeling Generalization, contains annual cohorts INS-W_1 through INS-W_4, collected during spring terms from 2018 through 2021 at a US research university. The dataset investigators report 155, 218, 137, and 195 annual participants, representing 705 person-years from 497 unique people. They collected phone data with an app built on the open-source AWARE mobile sensing framework and activity and sleep data with Fitbit, then released derived features processed with RAPIDS [20,21]. We obtained the supplied feature and survey files from the credentialed PhysioNet release [22]. No new participants were recruited for this secondary analysis.

The investigators recruited undergraduates by email and invited previous participants to return. Each study covered a 10-week spring quarter. Participants installed the app on their own phones, received a Fitbit, and completed prestudy, within-study, and poststudy surveys [20,21]. Smartphone ownership was not assigned. Individual demographic variables were unavailable in the supplied analytical files, preventing platform-specific demographic summaries and adjustment.

The release shifts dates by whole weeks to preserve privacy, within-person temporal order, and weekdays [20]. We used these dates for participant-specific survey alignment, not to compare external calendar events. Scheduled duration, released date span, and observed-day count are different quantities. An annual record represents one cohort contribution, not continuous observation for a calendar year.

Our feature sample comprised all annual identifiers in the released all-day feature tables that matched platform metadata. We validated one-to-one platform and survey joins and unique participant-date feature rows. The broader platform files contained 818 records, of which 113 had no corresponding feature record. Their absence is a coverage difference in the supplied files; we could not determine that it represented dropout. The "Results" section distinguishes metadata, feature, and screening samples.

The 705 annual records had 705 distinct literal identifier strings. Public overlap lists and their consuming code identified membership subsets but did not establish individual correspondence across years [23]. We therefore did not infer links from list position, identifier suffixes, or participant measurements. All inferential analyses and model splits were conducted within individual annual cohorts. We neither fitted pooled models assuming 705 independent people nor combined annual effects in an independence-based meta-analysis. Cross-year agreement is descriptive because some underlying people returned. A switcher count and a within-person platform-switching analysis could not be established from verified links.

Ethical Considerations

The original GLOBEM study received University of Washington Institutional Review Board approval (STUDY00003244), and participants provided informed consent before enrollment. Compensation was up to US $245 per quarter, depending on compliance [20,21]. The published consent forms described anonymized data sharing with university collaborators in 2018 and anonymous publication or disclosure to external researchers for further analysis and research in 2019-2021 [21]. We used the controlled-access, deidentified feature-level release and did not seek additional participant consent.

No separate ethics evaluation was undertaken for this secondary analysis. The rationale for not seeking additional review was that the analysis involved existing deidentified records, without participant interaction or access to direct identifiers. This rationale was informed by the definition of a human subject in the US Federal Policy for the Protection of Human Subjects (45 CFR 46.102(e)) [24]. The analysis was limited to existing, deidentified feature-level records released for research through controlled access, without participant recruitment, contact, or intervention. Access was obtained through PhysioNet registration and credentialing after completion of the required CITI Data or Specimens Only Research training, under the dataset's data-use agreement [20]. We did not have access to direct identifiers or attempt reidentification. Only aggregate findings are reported, and the supplementary materials exclude participant-level records and predictions. The source investigators restricted the release to derived features because sensor traces can reveal identities; deidentification does not eliminate all privacy risk [20].

Feature Definitions and Preprocessing

We retained the starting panel-selection rule: up to 6 all-day columns per sensor domain, selected alphabetically from keyword-matched candidates. This deterministic rule yielded 42 columns and did not use mental health outcomes or model performance. It contained 15 raw constructs, 13 normalized versions, and 14 discretized versions. We retained those raw constructs and added their 3 omitted counterparts for matched comparisons, yielding 45 columns. The raw constructs comprised 2 location features (home time and location entropy), 3 screen features (mean unlock duration overall, during exercise-classified locations, and during green-space locations), 2 Bluetooth counts, 2 incoming-call features, 2 connected-WiFi features, 2 Fitbit step summaries, and 2 Fitbit main-sleep summaries. Multimedia Appendix 1 defines each construct and records collection limitations, whereas Multimedia Appendix 2 supplies the complete column map and numerical outputs.

Alphabetical selection limits the panel's representativeness; other summaries could yield different domain contrasts. Holding

XSL•FO
RenderX

the 15 constructs fixed permits transformation comparisons without changing construct composition. We evaluated the 42-column panel as a supplementary diagnostic. The 45 matched columns represent 15 constructs in 3 forms, not independent measurements.

We distinguished 5 phone location/screen constructs from 4 Fitbit constructs. A core phone set contained home time, location entropy, and mean unlock duration without location context. The 2-event connectivity set contained total Bluetooth scans and incoming-call count. The 4-feature connectivity set additionally included scans of the least-frequently detected device and incoming calls from the most frequent contact. The latter contact feature was retained only as an artifact diagnostic: RAPIDS documentation states that iOS identifiers do not preserve repeated-contact identity [25]. It was excluded from downstream screening models.

Historical RAPIDS documentation also uses different screen-episode end points on Android and iOS [26]. Its Bluetooth provider documentation lists Android support, although the GLOBEM exports contain iOS values [27]. We could not verify the historical study-specific adaptation from derived features. Connected-WiFi documentation supports both platforms, but the supplied iOS WiFi values were entirely missing in the first 2 cohorts [28]. These observations preclude assuming that all iOS calls or Bluetooth values were absent, or attributing every observed contrast to a particular operating system restriction. Location estimates also depend on sampled records and feature construction [29].

Home time reflects sampled locations and inferred home, rather than self-reported withdrawal. Location entropy measures dispersion across observed locations in natural logarithm units. Mean unlock duration describes recorded episodes, not all attention to a phone. Bluetooth scans can repeatedly detect the same object; incoming-call counts depend on the events retained by the collection framework and do not measure all communication. Fitbit steps summarize recorded intraday intervals rather than total daily steps, and sleep measures describe wearable-estimated main sleep. The behavioral interpretation remains conditional on these definitions.

We averaged each feature over a participant's observed daily values, leaving an entirely unobserved feature missing. Each participant contributed equally to the between-person comparisons despite unequal observed-day counts. Zero remained a recorded value. Discretized labels (l/m/h or low/medium/high) were explicitly mapped to 0/1/2 before averaging; unrecognized labels triggered an error. The released discretized values are text labels, so generic numeric conversion would treat them as missing values rather than ordered categories. We used the supplied normalized and discretized features. The release defines normalization relative to each participant's median and 5th-to-95th percentile range, and discretization using participant-specific 33rd and 66th percentiles [20]. These are descriptions of released transformations, not transformations estimated from a prediction training fold.

These transformations are retrospective: their reference distributions may include observations outside a screening window, so they were excluded from downstream screening. Averaged ordinal codes describe the observed mix of low, middle, and high categories, not a recovered continuous behavioral scale. Ties and missing days can affect this summary.

Coverage and Feature Comparisons

For every feature and platform, we calculated the number of participants with any value, the proportion of missing released daily entries, observed days per participant, the proportion of observed values equal to zero, and within-person daily variance. The released tables contained 92, 97, 103, and 103 daily rows per participant across the 4 cohorts. These denominators describe the release, not verified sensor uptime or enrollment duration. A sensitivity analysis restricted dates to the interval between each participant's prestudy and poststudy questionnaires, inclusive. These questionnaire dates were not assumed to be exact enrollment boundaries.

Daily missingness divided missing entries by released daily rows; participant-level absence divided records lacking every daily value by the annual platform sample. Observed-day summaries included zero-day participants. Variance used at least 2 observations and the sample-variance denominator. Zero-valued observations remained observed, whereas missing values remained missing. Absent context-specific screen values could also reflect the absence of that context.

Within each cohort, we compared observed participant means with 2-sided Mann-Whitney tests and Cliff δ [30]. Cliff δ was defined as the probability that an iOS value exceeded an Android value minus the reverse probability; ties contributed zero. Negative values indicate lower iOS values. We used 2000 platform-stratified participant resamples for 95% percentile intervals. A bounded-difference interval replaced a degenerate bootstrap interval when all resampled estimates coincided. We applied Benjamini-Hochberg adjustment [31] separately within each cohort's raw, normalized, and discretized feature families; the latter 2 were exploratory. We did not classify small deltas as equivalence.

Cliff δ describes ordering on a −1 to 1 scale; medians and IQRs give original units. Entirely absent features were excluded from their observed-value comparisons.

Stratified resampling preserved platform counts and each person's joint feature vector. Complete empirical rank separation can yield a degenerate bootstrap distribution. The bounded-difference fallback avoids presenting that point mass as population certainty; its formula and derivation are in Multimedia Appendix 1. It does not correct selection or omitted-variable bias. Multiplicity adjustment was within cohort and feature family, without a claim of confirmatory testing or universal error control under arbitrary dependence.

To assess localization without treating correlated features as independent observations, we calculated the difference between the mean absolute Cliff δ in a fixed connectivity set and that in a fixed comparator set. Each participant resample preserved the full feature vector. The main phone-only contrast compared the 2-event connectivity set with the 3 core phone measures, excluding both Fitbit and the invalid contact-identity construct. Comparisons with all 5 phone behavioral measures, Fitbit, and

XSL•FO
RenderX

the 4 connectivity constructs were sensitivity analyses. Across-year averages of absolute deltas were descriptive and were kept distinct from absolute averages of signed deltas.

Platform Prediction and Missing-Data Sensitivity

We used fixed L2-penalized logistic regression (C=1; LIBLINEAR solver, as implemented in scikit-learn [32]) to predict iOS versus Android separately in each cohort. Models used 5 stratified folds, training-fold median imputation, and training-fold standardization. No hyperparameter selection was performed. An entirely missing training column was retained using the imputer's empty-feature handling. We calculated the area under the receiver operating characteristic curve (AUROC) from combined out-of-fold predictions, with iOS as the positive class. Values below 0.50 were reported without post hoc reversal.

Split seeds were identical across feature sets. Entirely missing training columns used the imputer's constant fallback, without held-out values.

Missingness-only models indicate entirely absent participant features, not intermittent daily absence. Missing-at-random assumptions cannot be established from observed rates alone [33].

Validation used one record per annual participant, matching the intended between-person comparison [34]. Bootstrap duplicates stayed together in a fold. We excluded leave-one-year-out validation because unidentified returning participants could occur in both training and evaluation years. No reported estimate represents validation in entirely new people at a new site or time.

The main matched comparison used 13 raw constructs excluding WiFi, their 13 normalized counterparts, and their 13 discretized counterparts. A distinct removal sequence contained 13 constructs, 12 after removing the contact feature, 10 after also removing both Bluetooth features, and 9 after removing the remaining incoming-call count. The final set comprised 5 phone behavioral and 4 Fitbit features. We also evaluated the 3 core phone measures, Fitbit alone, and indicators that participant-level features were entirely missing. WiFi-inclusive and 42-column models were diagnostic analyses rather than the primary comparison.

We repeated raw-panel classification in complete cases and compared all 3 transformations in participants complete on all 39 matched columns. Complete-case results refer to a selected population, so their difference from full-sample results cannot isolate the effect of imputation. For the main raw, normalized, discretized, and 9-feature behavioral models, uncertainty used 500 participant bootstrap samples with preprocessing and cross-validation refitted. Missingness-only and raw complete-case classifiers also used refitted resamples. Duplicate copies of a resampled participant stayed together in a fold. Other diagnostic models, including common-complete-case transformation comparisons, used conditional resampling of fixed out-of-fold predictions, explicitly labeled in the supplementary outputs. No interval treated 5-fold scores as 5 independent observations. Intervals are approximate, conditional on the observed stratum sizes, and can be unstable with small platform groups or near-perfect rankings.

Requiring all 39 columns holds participants constant across transformations. Complete-record logistic coefficients can be unbiased under specified missingness structures [35], but this does not guarantee representative AUROC. Platform-specific retention therefore remains part of the interpretation.

Overlapping training sets make fold errors dependent [36]. The outputs identify the resampling method and usable replicates; conditional intervals omit model-refitting variation.

Psychological Comparisons and Adjustment

We compared prestudy loneliness, perceived stress, resilience, emotion-regulation reappraisal and suppression, and depressive symptoms across platforms using the released common-version scores. Cohort-specific anxiety scores were compared separately: the State-Trait Anxiety Inventory–State (STAI-S) score in the first cohort and the released State-Trait Anxiety Inventory (STAI) score in the remaining cohorts. Benjamini-Hochberg adjustment covered the 7 score comparisons within each cohort. We did not interpret nonsignificant tests as psychological equivalence.

The common adjustment set comprised the 10-item University of California, Los Angeles Loneliness Scale (UCLA-10), the 10-item Perceived Stress Scale (PSS-10), the Brief Resilience Scale (BRS), Emotion Regulation Questionnaire (ERQ) reappraisal and suppression scores, and the released 9-item Center for Epidemiologic Studies Depression (CESD-9) score. Higher scores indicate more of the named construct: greater loneliness, perceived stress, resilience, reappraisal, suppression, or depressive symptoms, respectively. Anxiety used the cohort-specific released instrument rather than assuming that the state and other anxiety versions were identical. We analyzed the supplied scores, without reconstructing questionnaire items or claiming new psychometric validation in this sample.

For total Bluetooth scans and incoming-call counts, we regressed the standardized log (1 + participant mean) on an iOS indicator, first without and then with the 6 common standardized psychological scores. Both models used the same complete-case sample within each cohort. We used ordinary least squares with heteroskedasticity-consistent SEs using the HC3 covariance estimator and t-based intervals [37]. An additional specification included the cohort-specific anxiety score. The contact feature was analyzed separately as an artifact diagnostic. We checked model rank, conditioning, and leverage. This analysis tests sensitivity to measured psychological adjustment; it does not control for income, age, device price, or other unavailable ownership-related characteristics.

Android was the reference category. Coefficients describe SD differences in log-transformed participant means, not raw-count differences. Psychological coefficients were not treated as mediators.

We quantified sensitivity of the adjusted platform coefficients to omitted variables using the point-null robustness value of Cinelli and Hazlett [38]. We refitted the same regressions with classical ordinary least squares covariance for this calculation;

XSL•FO
RenderX

the main coefficient intervals retain HC3 covariance. The robustness value summarizes the equal partial R-squared an omitted factor would need with platform and the outcome, conditional on the specified controls, to explain away the coefficient. It does not estimate actual demographic confounding or test the measurement mechanism. Multimedia Appendix 1 gives the formula and assumptions.

Exploratory Depressive-Symptom Screening

We used the released end-of-term Beck Depression Inventory-II (BDI-II) label, defined by a score greater than 13, as a symptom-screening outcome rather than a clinical diagnosis. We verified agreement between the released label and the score threshold. Predictors were means of raw daily features from the 14 calendar days strictly before the questionnaire date. A feature required at least 7 observed days in that window. Participants were eligible if at least 1 of the 9 candidate predictors met this criterion. Models therefore shared an eligibility rule, with remaining missing features imputed within training folds.

A common end-of-term measure avoided mixing heterogeneous weekly targets, including the first cohort's derived labels [20]. Neither the 14-day window nor the 7-day rule was tuned against performance. Requiring one qualifying predictor retained partial multimodal records, making missingness part of the evaluated use case.

The behavioral model included the 3 core phone measures and 4 Fitbit measures. We compared this with a model adding total Bluetooth scans and incoming-call count, then a model additionally including platform. Intercept-only, platform-only, and core-phone models were supplementary comparators. Contact identity, across-dataset device-selection features, context-specific screen features, and WiFi were excluded. We used the same fixed classifier and participant-level folds, stratifying jointly by outcome and platform in 2019 to 2021 and by outcome alone in 2018, when the smallest joint subgroup had only 2 records.

We reported overall and platform-specific AUROC, average precision, Brier score, log loss, symptom prevalence, and mean predicted probability. Calibration-in-the-large was estimated only in groups with at least 20 participants and at least 5 positive and 5 negative outcomes. Paired participant resampling with model refitting estimated changes after adding connectivity and platform. Resampling preserved outcome-by-platform stratum counts, limiting the uncertainty represented for prevalence and calibration. We used Fisher exact tests for platform versus screening-label associations and, separately, for metadata records lacking all feature records. The latter 4 exploratory tests are reported without multiplicity adjustment. These exploratory models evaluate retrospective screening; presurvey feature windows do not establish prospective validity because upstream released feature construction can use broader participant context.

AUROC measures ranking, whereas average precision depends on outcome prevalence and summarizes precision across recall [39]. Brier score measures squared probability error; log loss penalizes confident errors. Lower values of both are preferable. Metrics used held-out predictions, without selecting a clinical referral threshold.

We estimated calibration-in-the-large by fitting a logistic intercept with the logit of held-out probability as an offset, fixing its coefficient at 1 [40]. We also reported observed/expected ratios, calculated as observed positive outcomes divided by the sum of predicted probabilities. Ideal values are 0 and 1, respectively. These are descriptive estimates without CIs. The minimum-size rule applied to the intercept fit; ratios remained reportable in smaller groups but were treated as unstable. Jointly estimated calibration slopes are retained in the electronic outputs as a separate diagnostic.

Reproducibility

The analysis used Python (version 3.12; Python Software Foundation), *NumPy* 2.5.3, *pandas* 3.0.6, *SciPy* 1.18.1, *scikit-learn* 1.9.1, and *statsmodels* 0.15.0. Multimedia Appendix 2 contains the executable pipeline, pinned dependencies, concise execution instructions, table-export scripts, and aggregate results. We checked sample counts, ordinal decoding, joins, Cliff δ, HC3 estimates, end point windows, and out-of-fold predictions through separate reconstructions. The "Methods" section describes the exploratory design and statistical assumptions; the study was not preregistered. Participant-level source data and intermediate predictions are not redistributed. Multimedia Appendix 3 maps the reporting items to their manuscript locations.

Results

Sample and Feature Availability

The feature sample contained 554 iOS and 151 Android annual records; Android represented 21.4% of 705 records. Its annual share ranged from 6.5% to 27.1% (Table 1). There were 669 records with end-of-term labels and 661 eligible screening windows.

XSL•FO
RenderX

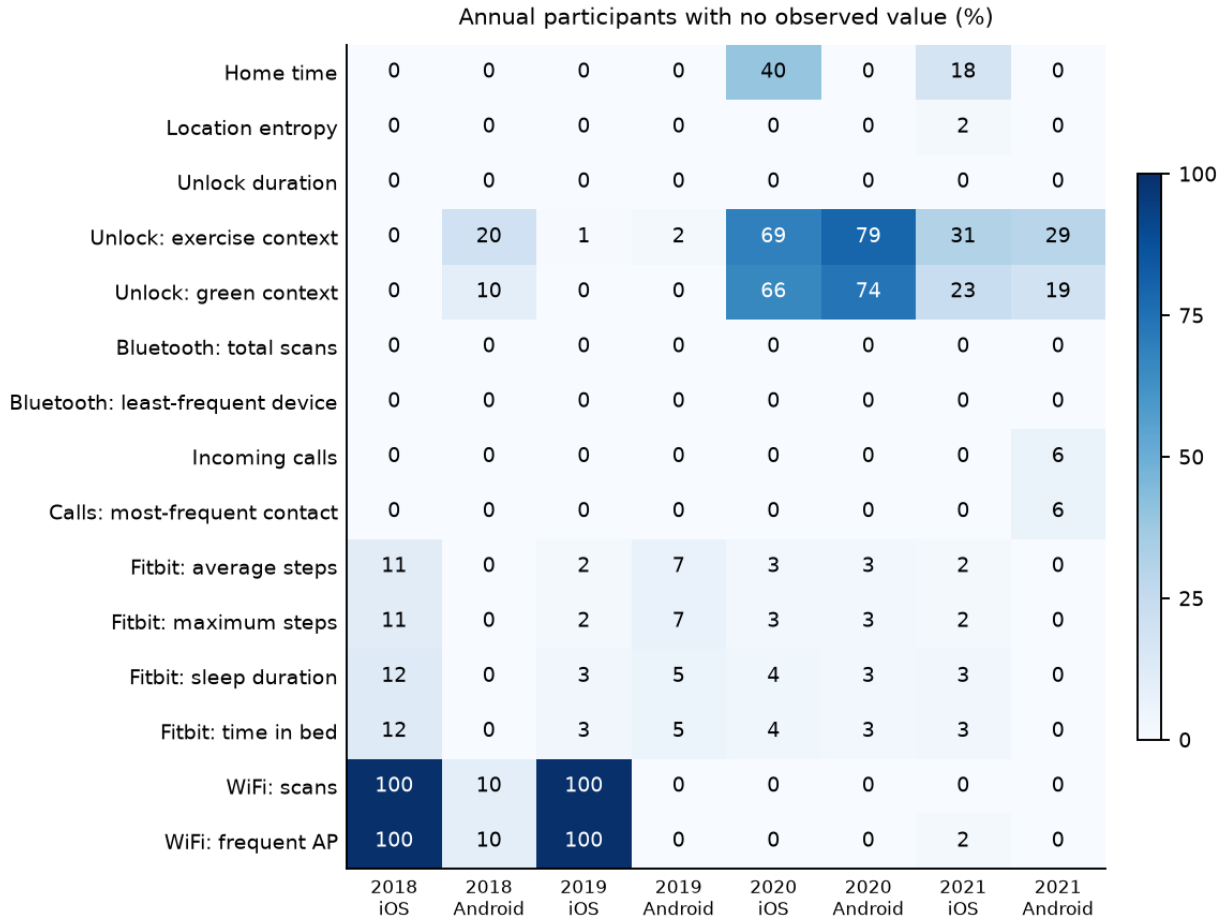

Table 1. Sample flow by platform in the secondary analysis of 4 Generalization of Longitudinal Behavior Modeling US college cohorts, 2018 to 2021[a].

Year	Platform	Metadata, n	Features, n	End-term label, n	Eligible screening, n
2018	iOS	160	145	132	131
2018	Android	41	10	10	10
2019	iOS	172	159	153	152
2019	Android	76	59	50	49
2020	iOS	114	103	102	98
2020	Android	44	34	33	33
2021	iOS	153	147	141	140
2021	Android	58	48	48	48

[a]Feature sample: 705 annual records, including 554 iOS and 151 Android (21.4%). The source reports 497 underlying people. Of 818 metadata records, 113 had no feature record; the reason is unknown. End-term labels were present for 669 feature records; 661 met the 14-day screening eligibility rule. Annual totals are not counts of distinct people across years. End-term label: Beck Depression Inventory-II score greater than 13.

Missingness differed by feature, platform, and cohort, rather than following a uniform phone-versus-wearable pattern (Figure 1; Multimedia Appendices 1 and 2). In Figure 1, absence means no value across all released daily rows, with denominators set by the annual iOS/Android samples of 145/10, 159/59, 103/34, and 147/48 for 2018 to 2021. Percentages are rounded to whole numbers, so 0% does not imply complete daily coverage. Fitbit features are wearable-derived; all others are phone-derived. This measure of missingness does not capture sensor uptime or verified enrollment coverage.

Figure 1. Participants with no observed daily value for each raw feature in a secondary analysis of Generalization of Longitudinal Behavior Modeling US college cohorts, 2018 to 2021. AP: access point.

Home time was entirely missing for 41 of 103 iOS records in 2020 and 26 of 147 in 2021, compared with 0 of 34 and 0 of 48 Android records, respectively. Both WiFi constructs were entirely absent from iOS observations in 2018 and 2019,

XSL•FO
RenderX

whereas at least one value was available for 9 of 10 and 59 of 59 Android records. Context-specific screen features also had limited coverage. Observed-day counts and within-person variance are reported separately from participant means; none of these summaries establishes equal measurement reliability.

Metadata-to-feature loss was greater for Android in every cohort. Missing feature records numbered 15/160 iOS versus 31/41 Android in 2018 (9.4% vs 75.6%; $P<.001$), 13/172 versus 17/76 in 2019 (7.6% vs 22.4%; $P=.002$), 11/114 versus 10/44 in 2020 (9.6% vs 22.7%; $P=.04$), and 6/153 versus 10/58 in 2021 (3.9% vs 17.2%; $P=.002$). These unadjusted Fisher tests describe availability in the supplied files; the cause of absence is unknown (Table S12 in Multimedia Appendix 1).

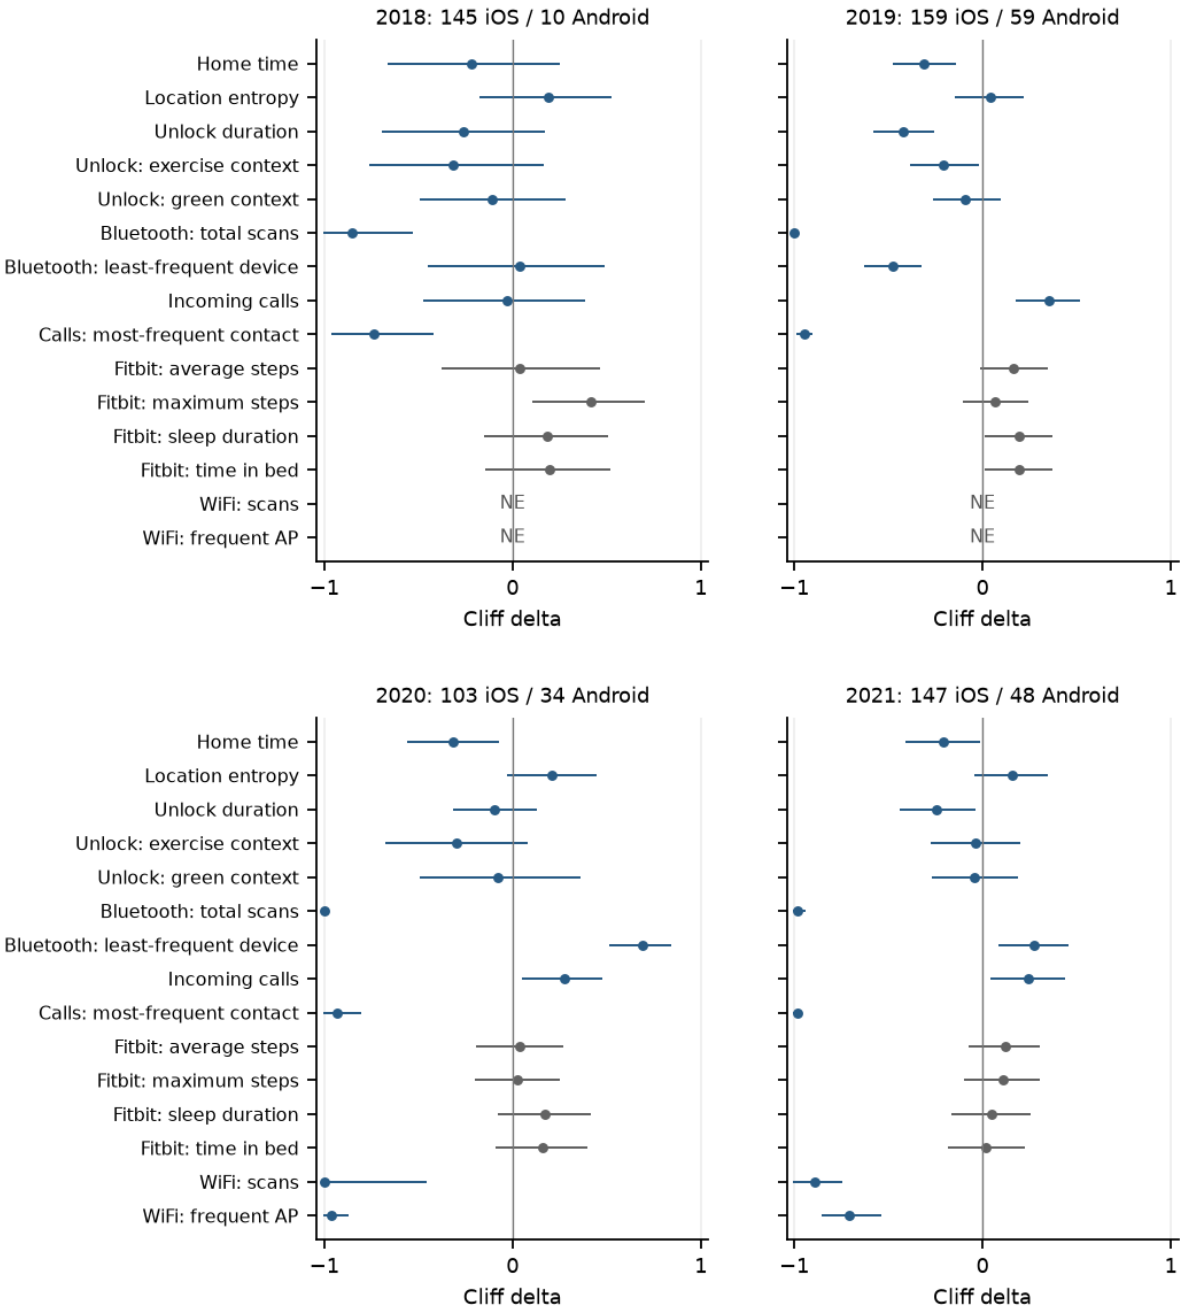
Total Bluetooth scans were observed for every annual participant on both platforms, with no zeros among observed daily values. Participant-level median imputation was therefore never triggered for this feature. Daily missingness was 31.0% versus 32.0% (iOS vs Android) in 2018, 22.1% versus 28.9% in 2019, 54.2% versus 31.5% in 2020, and 33.5% versus 28.1% in 2021 (Table S11 in Multimedia Appendix 1). Intermittent missingness could still affect participant means. Missingness-only classifier AUROCs ranged from 0.50 to 0.69. The 2020 observed-value home-time contrast uses 62 of 103 iOS records; smaller differences among retained observations do not resolve the missing-data problem.

Magnitude and Localization of Platform Differences

Total Bluetooth scan counts were lower on iOS in all 4 cohorts, with signed Cliff δ from −1.00 to −0.85. Home-time Cliff δ were also negative in every cohort, ranging from −0.32 to −0.21. The broader pattern contained smaller, variable, and sometimes reversed differences in other features. We did not combine these annual estimates into a pooled inferential effect.

The phone-only contrast comparing total Bluetooth and incoming-call counts with home time, entropy, and unlock duration was positive in each cohort. Differences in mean absolute Cliff δ ranged from 0.22 to 0.43, with all 4 participant-resampling intervals excluding zero (Table 2). This result does not depend on including Fitbit in the comparator or on the contact-identity artifact. It describes the selected feature panels, not all possible connectivity and behavioral constructs.

Table 2. Bluetooth counts and a phone-only feature contrast in 4 Generalization of Longitudinal Behavior Modeling US college cohorts, 2018 to 2021[a].



Year	iOS, n; median (IQR)	Android, n; median (IQR)	Bluetooth, Cliff δ (95% CI)	Phone-only contrast, mean absolute Cliff δ (95% CI)
2018	145; 39.3 (28.4 to 57.5)	10; 720.9 (380.8 to 1145.8)	−0.850 (−1.000 to −0.532)	0.216 (0.021 to 0.475)
2019	159; 126.8 (91.5 to 177.3)	59; 4413.3 (2735.6 to 5439.4)	−0.999 (−1.000 to −0.997)	0.416 (0.291 to 0.515)
2020	103; 5.2 (3.0 to 21.4)	34; 588.4 (445.7 to 1434.5)	−0.997 (−1.000 to −0.990)	0.427 (0.242 to 0.582)
2021	147; 12.5 (6.1 to 26.6)	48; 877.5 (324.6 to 1567.5)	−0.980 (−1.000 to −0.943)	0.409 (0.253 to 0.562)

[a]Medians and IQRs are across participant means of daily total Bluetooth scans. Cliff δ is Pr(iOS>Android) minus Pr(iOS<Android); negative values indicate lower iOS values. The phone-only contrast is mean absolute Cliff δ for total Bluetooth scans and incoming-call count minus that for home time, location entropy, and mean unlock duration. Fitbit and contact identity are excluded. Intervals use 2000 within-cohort participant resamples; overlapping people preclude independent cross-year pooling.

Figure 2 summarizes observed-value contrasts across the selected phone (blue) and Fitbit (gray) constructs. Each point is a Cliff δ, positive when iOS values are higher, and each bar is a within-cohort 95% participant-resampling interval, with a conservative bounded fallback where the bootstrap interval was degenerate. Annual platform counts appear above each panel; observed counts vary by feature and are supplied in Multimedia Appendix 2. WiFi contrasts are not estimable where iOS values are wholly missing. Because the annual cohorts share people, the panels are not independent replications.

Figure 2. Platform differences in observed participant means of raw sensing features in Generalization of Longitudinal Behavior Modeling US college cohorts, 2018 to 2021. AP: access point; NE: not estimable.

Platform Prediction and Transformations

The 13 raw constructs classified platform with out-of-fold AUROC of 0.94, 0.99, 0.997, and 0.98 across the 4 cohorts (Table 3). The 2020 estimate was below 1. Tables distinguish near-perfect rankings from exact observed rank separation. Removing all 4 connectivity constructs yielded 9-feature behavioral AUROCs of 0.78, 0.68, 0.41, and 0.48. These results do not support describing all behavioral-only models as chance classifiers or the retained features as platform-neutral.

XSL•FO
RenderX

Table 3. Out-of-fold platform area under the receiver operating characteristic curve and 95% intervals for matched transformations and behavioral features in 4 Generalization of Longitudinal Behavior Modeling US college cohorts, 2018 to 2021[a].

Year	Raw, 13	Normalized, 13	Discretized, 13	Behavioral, 9
2018	0.94 (0.78-1.00)	0.34 (0.08-0.76)	0.65 (0.24-0.84)	0.78 (0.36-0.90)
2019	0.99 (0.98-1.00)	0.91 (0.80-0.95)	0.72 (0.57-0.80)	0.68 (0.53-0.76)
2020	0.997 (0.907-1.000)	0.87 (0.70-0.94)	0.73 (0.62-0.85)	0.41 (0.26-0.64)
2021	0.98 (0.92-1.00)	0.91 (0.79-0.97)	0.80 (0.70-0.88)	0.48 (0.34-0.66)

[a]Cohort sizes are 155, 218, 137, and 195. Positive class: iOS. The 13-construct panels exclude WiFi; raw, normalized, and discretized columns represent the same constructs. The 9-feature panel contains 5 phone location/screen and 4 Fitbit features. All use fixed L2 logistic regression, 5 folds, and training-fold imputation/scaling. Intervals use 500 participant resamples with preprocessing and cross-validation refitted. They are approximate, conditional on observed platform counts. Estimates at or above 0.995 use 3 decimals; an asterisk marks an exact AUROC of 1 in the evaluated predictions. A boundary interval is conditional on the observed sample and does not certify future performance.

Matched normalized AUROCs were 0.34, 0.91, 0.87, and 0.91; discretized AUROCs were 0.65, 0.72, 0.73, and 0.80. Discretization yielded lower platform discrimination in every cohort. The first normalized estimate had a wide interval and only 10 Android records.

Missingness-only AUROC ranged from 0.50 to 0.69. Complete cases for the raw 13-construct panel numbered 135, 206, 23, and 115; the 2020 subset contained only 18 iOS and 5 Android records. Multimedia Appendix 1 reports complete-case models, the distinct removal steps, and sensitivity analyses using the 42-column panel. Multimedia Appendix 2 includes all conditional and refitted intervals and the questionnaire-bounded sensitivity results. The complete-case restriction markedly changed the available sample, especially in 2020.

Raw complete-case AUROCs were 0.89 (95% CI 0.70-1.00), 1.000* (0.994-1.000), 0.97 (0.82-1.00), and 0.99 (0.89-1.00), with refitted intervals. The asterisk marks an exact AUROC of 1 in the evaluated 2019 predictions. Requiring all 39 columns retained the same people, but used conditional intervals (Table S5 in Multimedia Appendix 1). In 2020, normalized AUROC was 0.48 among 23 complete cases versus 0.87 among all 137 records.

Restricting aggregation to dates between each participant's prestudy and poststudy questionnaires retained 143, 205, 131, and 189 annual records. Raw-panel AUROCs remained 0.93, 1.00, 0.99, and 0.98, with the 2019 unrounded estimate below 1. The corresponding 9-feature behavioral AUROCs were 0.74, 0.69, 0.42, and 0.53. Table S9 in Multimedia Appendix 1 supplies conditional intervals for this sensitivity analysis. Core-phone and Fitbit-only classifier results are reported separately in Table S4 in Multimedia Appendix 1, preserving the distinction between phone-derived behavior and wearable measurements.

Paired comparisons qualify the transformation results. In 2021, normalized minus raw AUROC was −0.066 (95% CI −0.191 to 0.014), so a reduction was not established in that cohort. Table S13 in Multimedia Appendix 1 reports every paired transformation contrast with its sign defined consistently. Below-chance estimates, including normalized AUROC 0.34 in 2018, are evaluated without reversing predictions or relabeling classes; small samples and unstable cross-validation can yield such values without establishing a reproducible inverse relationship.

Psychological Measures and Adjusted Feature Differences

None of the 7 psychological-score comparisons met the within-cohort 5% Benjamini-Hochberg threshold. The estimated differences and intervals remain relevant because the absence of a detected difference is not equivalence. Multimedia Appendix 1 reports distributions and effect sizes.

After adjustment for the 6 common psychological scores, the iOS coefficient for standardized log Bluetooth counts was −2.95, −2.12, −1.99, and −2.00 across the 4 cohorts, with all 4 intervals below zero (Table 4). The corresponding samples were 153, 216, 133, and 194. Incoming-call results differed from the contact-specific diagnostic and are reported separately. These estimates establish persistence under the specified adjustment, not that platform choice or sensing behavior is independent of personal characteristics.

XSL•FO
RenderX

Table 4. Cohort-specific platform coefficients before and after psychological adjustment in Generalization of Longitudinal Behavior Modeling US college students, 2018 to 2021[a].

Year	Outcome	n (iOS/Android)	Unadjusted β (95% CI)	Adjusted β (95% CI)	Adjusted *P*
2018	Bluetooth scans	153 (143/10)	−2.85 (−3.79 to −1.92)	−2.95 (−3.87 to −2.03)	<.001
2018	Incoming calls	153 (143/10)	−0.28 (−1.28 to 0.72)	−0.32 (−1.30 to 0.67)	.52
2019	Bluetooth scans	216 (159/57)	−2.12 (−2.24 to −2.01)	−2.12 (−2.24 to −2.01)	<.001
2019	Incoming calls	216 (159/57)	0.64 (0.38 to 0.89)	0.56 (0.30 to 0.82)	<.001
2020	Bluetooth scans	133 (99/34)	−2.00 (−2.17 to −1.83)	−1.99 (−2.15 to −1.83)	<.001
2020	Incoming calls	133 (99/34)	0.47 (0.13 to 0.81)	0.38 (0.05 to 0.70)	.02
2021	Bluetooth scans	194 (146/48)	−2.01 (−2.20 to −1.82)	−2.00 (−2.19 to −1.81)	<.001
2021	Incoming calls	191 (146/45)	0.38 (0.06 to 0.71)	0.34 (0.00 to 0.67)	.048

[a]Outcome units are SDs of log (1 + participant-mean count), standardized in the analysis sample. Android is the reference category. Models include an intercept; adjusted models add standardized prestudy 10-item University of California, Los Angeles Loneliness Scale (UCLA-10), 10-item Perceived Stress Scale (PSS-10), Brief Resilience Scale, Emotion Regulation Questionnaire reappraisal, Emotion Regulation Questionnaire suppression, and 9-item Center for Epidemiologic Studies Depression (CESD-9). Unadjusted and adjusted models use identical complete cases. Intervals and *P* values use HC3 covariance and t inference within cohort. No pooled model or cross-year person clustering is claimed. Anxiety sensitivity and contact-identity diagnostic models are in Multimedia Appendix 2.

The incoming-call coefficient was −0.32 (95% CI −1.30 to 0.67) in 2018 and positive in the 3 later cohorts after adjustment (Table 4). The 2021 incoming-call model included 191 records because 3 Android records lacked the outcome feature; its Bluetooth counterpart included 194. All primary adjusted design matrices had full rank, with 8 parameters, and residual degrees of freedom ranged from 125 to 208. Electronic outputs report anxiety-adjusted models and the most-frequent-contact diagnostic separately.

Point-null robustness values for the adjusted Bluetooth coefficient were 0.636, 0.892, 0.809, and 0.793, compared with 0.075, 0.234, 0.164, and 0.135 for incoming calls (Table S14 in Multimedia Appendix 1). These values concern equal-strength omitted associations under linear regression, not the probability of an unmeasured explanation.

Across the primary adjusted Bluetooth and incoming-call models, design-matrix condition numbers ranged from 4.57 to 9.56 and maximum observation leverage from 0.129 to 0.181. The complete diagnostic records accompany the coefficient estimates in Multimedia Appendix 2.

Exploratory Screening Performance

The 661 eligible annual windows comprised 141, 201, 131, and 188 records. Within these samples, the platform-versus-symptom-label Fisher tests had *P* values of .33, .87, .42, and .31. The first cohort's Android subgroup contained only 2 positive labels among 10 records. Subgroup estimates were therefore particularly uncertain, and its calibration-in-the-large was not estimated.

Positive symptom screens numbered 51 of 141 (36.2%), 86 of 201 (42.8%), 52 of 131 (39.7%), and 75 of 188 (39.9%). For the model including connectivity, the corresponding mean held-out predicted probabilities were 36.8%, 43.4%, 40.6%, and 40.0%. These summaries describe annual screening records; they do not count distinct diagnosed people across cohorts.

The 7-feature behavioral screening models had overall AUROCs of approximately 0.41 to 0.56. Adding total Bluetooth and incoming-call counts changed AUROC by 0.029, 0.023, 0.004, and 0.034; all paired 95% intervals included zero (Table 5). Adding platform to those models also produced intervals spanning zero. Supplementary results report Brier scores, log loss, average precision, platform-specific performance, and calibration. The models did not show consistently useful discrimination or establish a detrimental effect of connectivity features on screening.

XSL•FO
RenderX

Table 5. Exploratory end-of-term depressive-symptom screening in eligible Generalization of Longitudinal Behavior Modeling US college students, 2018 to 2021[a].

Year	n	Behavioral model AUROC[b]	Behavioral + connectivity model AUROC	Behavioral + connectivity + platform model AUROC	Connectivity AUROC change (95% CI)
2018	141	0.56	0.59	0.58	0.029 (−0.045 to 0.088)
2019	201	0.41	0.43	0.41	0.023 (−0.059 to 0.087)
2020	131	0.54	0.54	0.54	0.004 (−0.077 to 0.072)
2021	188	0.52	0.55	0.54	0.034 (−0.036 to 0.101)

[a]Outcome: BDI-II >13. Raw feature means cover the preceding 14 days, excluding the survey date, with at least 7 observations per feature. The behavioral model uses 3 core phone and 4 Fitbit features; connectivity adds total Bluetooth scans and incoming-call count; the final model also adds platform. Cohort models use the same eligible records and folds. Change is connectivity model minus behavioral model. Intervals refit preprocessing and models in 500 paired participant resamples. These are retrospective screening comparisons, not diagnoses, equivalence tests, or causal platform effects. Subgroup and calibration results are supplied in Multimedia Appendices 1 and 2.

[b]AUROC: area under the receiver operating characteristic curve.

All 3 substantive screening models had worse Brier scores than the intercept-only benchmark in each cohort. For the model including connectivity, scores were 0.233, 0.257, 0.260, and 0.253, compared with 0.231, 0.245, 0.240, and 0.240 for the benchmark. These descriptive comparisons do not establish population-level inferiority. Paired Brier-score intervals for connectivity and platform additions included zero throughout (Table S8 in Multimedia Appendix 1). Joint calibration slopes for the connectivity model were 0.39, −1.03, −0.07, and 0.04, indicating unstable or weak probability ordering.

Adding connectivity shifted Android mean predicted risk without an established AUROC gain. Android observed/expected ratios moved from 0.504 to 0.953 in 2018 (10 records), from 0.893 to 0.965 in 2019, and from 0.779 to 0.996 in 2021, but from 0.875 to 0.800 in 2020. The direction was inconsistent across cohorts, and these fixed-prediction estimates have no uncertainty intervals. They do not establish better subgroup calibration in a new sample. Table S7 in Multimedia Appendix 1 reports calibration-in-the-large and observed/expected ratios for both models and all platform groups.

Discussion

Principal Findings

Within GLOBEM, selected connectivity features carried more platform-associated variation than core phone behavioral measures, including after Fitbit features were considered separately. For mHealth apps that interpret communication or proximity as indicators of social engagement, recorded values must therefore be considered alongside their collection methods. A low Bluetooth count cannot, by itself, distinguish limited nearby-device exposure from limited observation. This finding supports feature-specific assessment before clinical interpretation, rather than treating all passive sensing as unreliable.

Smaller location and screen contrasts did not establish comparable monitoring across platforms. Home-time differences were directionally consistent, behavioral features retained platform information in some cohorts, and location-feature coverage differed between iOS and Android. In mobile monitoring between clinical assessments, an unavailable home-time feature must be distinguished from an observed low value. Similar averages among available records do not establish that an app observes behavior equally consistently on both systems.

The depressive-symptom screening experiment did not demonstrate deterioration after adding connectivity features, but weak baseline discrimination and wide paired intervals prevented conclusions about clinical usefulness or absence of harm. For mobile and ubiquitous mental health monitoring, these results support evaluating platform-specific coverage alongside performance for the intended clinical outcome. Before sensing-derived risk estimates inform follow-up or referral, their calibration and usefulness require assessment in the intended population and use case [14,15].

What the Platform Contrast Identifies

Bluetooth counts combine nearby-device exposure, scan opportunity, and feature construction. Ownership-related behavior could affect exposure; hardware and software could affect observation. These components were not observed separately. Near separation of released values therefore does not identify how much of the contrast belongs to operating-system policy, the app, the provider, or behavior.

Contact identity presents a documented construct mismatch. Without stable identifiers, repeated contacts cannot support the same social-network statistic across platforms. Exclusion from shared substantive models follows from the feature definition, not its coefficient size. Total incoming events do not require persistent contact identity. Their direction also differed: iOS values were higher in 2019 to 2021, inconsistent with a blanket claim that iOS call observations were absent. Vendor and AWARE-iOS documentation distinguish restrictions on scanning or identity from the ability to observe call events (Multimedia Appendix 1). The exact historical implementation remains unverified; third-party calling services cannot be assigned responsibility from these exports.

Implications for mHealth Measurement

Individualization can remove a stable additive offset through baseline subtraction, or a stable multiplicative difference through rescaling under suitable assumptions. It cannot restore

XSL•FO
RenderX

unrecorded events or lost contact identity. If observation changes with charging, phone state, or behavior, a fixed baseline may remain inadequate. The daily exports do not distinguish these mechanisms. With far fewer recorded Bluetooth events on iOS, centering also leaves different observation counts. It cannot be assumed to equalize measurement noise or preserve equally precise deviations from each person's baseline.

Discretization can reduce scale differences while discarding distances relevant to symptoms. Lower platform AUROC is therefore insufficient grounds for choosing a mental health representation. Validation should compare retained outcome information and measurement stability using a baseline available before prediction. Our retrospective transformation comparison leaves that prospective question open, especially after a device replacement or software update.

Smaller behavioral contrasts can prioritize features for validation without establishing interchangeability. Paired-device or reference observations would separate agreement from merely similar averages, consistent with measurement-comparison methodology [41]. Observed daily variance mixes behavioral fluctuation with measurement variation. It cannot substitute for repeated reference measurements of the same underlying behavior.

Textbox 1 summarizes practical checks that follow from these findings. Bluetooth scan counts should be excluded from a shared clinical interpretation when comparable observation cannot be justified, or retained as an explicitly evaluated sensitivity input pending measurement validation. This conditional recommendation differs from automatic removal of every connectivity feature. Software and collection choices restrict which scientific questions released traces can answer [42].

These are measurement and reporting checks, not evidence that any resulting screening model is clinically validated.

Textbox 1. Platform audit steps for passive-sensing mobile health studies.

Audit step
• Report platform counts at enrollment, feature availability, and outcome-model eligibility; account for losses between these samples.
• Separate observed zeros, intermittently missing days, entirely absent participant features, and structural noncollection. Report their denominators by platform.
• Verify event definitions and collection capabilities. Exclude or redefine constructs that cannot represent the same quantity on both platforms.
• Use platform classification as a measurement diagnostic, with matched constructs, participant-disjoint validation, and explicit missing-data checks.
• Evaluate the intended health outcome against an intercept benchmark. Compare calibration and probability error by platform alongside discrimination and uncertainty.
• Record operating system, app, hardware, and feature-provider versions, and repeat validation after consequential changes.

Relation to Prior Evidence

Platform variation is a candidate explanation for generalization difficulties, not a demonstrated cause of them [12,13]. Platform-specific modeling also has precedent: Lu and colleagues [43] fitted separate iOS and Android depression models to handle device-platform differences. Earlier connectivity-based symptom studies establish relevance, rather than validating every implementation [2,3]. Location-feature associations have also varied with weekday versus weekend aggregation [44]. Replication needs comparable sources, operational definitions, and observation windows, not just matching column labels.

Currey and Torous [45] found weak passive-only prediction and variation with analytical subset and coverage restriction. In an mHealth study involving depression and diabetes, complete-case deletion retained 950 of 2694 participant-days [46]. Neither study tests GLOBEM's mechanism. They illustrate why apparent feature quality, evaluated sample, and prediction performance must be considered together.

Cross-study coverage findings also caution against ranking platforms universally. Kiang and colleagues [47] found lower GPS noncollection on iOS across 6 digital-phenotyping studies, unlike the iOS home-time absence observed here. Raw GPS noncollection and absence of a derived home-time feature are different endpoints, collected with different systems. This contrast supports conditional interpretation, not a contradiction that either dataset alone can resolve. Shared Fitbit hardware removes one phone-sensor difference by design but does not validate every wearable output in GLOBEM.

Interpreting the Downstream Experiment

The fixed screening model made feature additions comparable but left nonlinear and personalized models untested. Weak baseline discrimination means the behavioral panel did not clearly recover the target symptom signal. Small incremental changes could reflect weak relevance, redundancy, sampling variation, or model misspecification. The null cannot distinguish these explanations. The GLOBEM benchmark also reported weak generalization, but its 2-institution datasets, feature sets, and validation tasks differ from this end-of-term experiment [13]. It cannot establish that weak screening performance here is an inevitable property of these cohorts.

A ranking improvement can coexist with poor calibration or higher probability error [40]. Clinical usefulness also depends on the consequences of decisions at specified thresholds [48]. Our models justify neither a referral cutoff nor a claim of improved patient care. Such evaluation requires a defined clinical action and an appropriate reference outcome.

XSL•FO
RenderX

Small platform groups and missing demographics constrain subgroup interpretation. Similar point estimates would not establish equal errors or benefit without adequate evaluation of specified clinical decisions.

Limitations

The platform was not randomized, and income, age, device price, and related demographic attributes were unavailable. For example, if a characteristic associated with iOS ownership also increased time away from home, it could contribute to the negative home-time contrast; the opposite behavioral association could attenuate that contrast. Direction cannot be assigned without those measurements. The Bluetooth robustness values quantify the strength of omitted associations required under the fitted linear specification, but cannot label socioeconomic explanations implausible or identify a device mechanism. They neither cover arbitrary nonlinear misspecification nor remedy selection into the available-feature sample. Demographics are available from the custodians by special request; none was supplied.

Verified cross-year person links were unavailable. Conducting analyses separately by cohort avoids fitting models that assume repeated annual records are independent, but prevents estimation of person-level random intercepts across years and within-person platform changes. The same individuals may contribute to several annual findings, so consistency across years is not independent replication. We cannot infer that there were no platform switchers. A custodian-provided cross-walk is needed for those analyses.

This is a selected college population from one US institution using one collection and processing system during 2018 to 2021. Platform ratios, hardware, operating system versions, app configurations, and user behavior may differ elsewhere. Android metadata records were more often absent from the feature files, particularly in 2018. If this reflects collection failure, the retained Android sample would selectively represent devices with recorded data. The cause is unknown, so contrasts characterize retained records rather than all enrolled phone owners. The first cohort included only 10 Android records. Complete-case selection was especially severe in 2020 and could change both effect magnitude and classifier performance. These factors limit precision and transportability, including to Android-majority settings.

The release provides derived features rather than the raw observation process. Observed days and within-person variance are coverage diagnostics, not estimates of sensor accuracy or test-retest reliability. The released date range does not identify exact enrollment, and upstream feature construction can depend on participant-level context beyond a prediction window. The historical Bluetooth implementation and context-specific screen construction could not be fully verified. Our results apply to these exports and cannot attribute every difference to the operating system alone.

The alphabetical panel rule did not prioritize commonly modeled unlock counts, unique Bluetooth devices, or outgoing calls. Holding constructs fixed makes transformation comparisons interpretable, but cannot establish that these constructs represent their domains. The screening experiment used one fixed model family, a limited feature panel, one thresholded symptom measure, and one retrospectively defined window. It did not assess diagnosis, onset forecasting, intervention effects, or deployment under a new platform distribution. Small outcome-by-platform groups constrained calibration and subgroup comparisons. Bootstrap intervals are approximate and conditional on observed stratum counts; they do not capture all uncertainty in prevalence, model specification, or a new setting. Nonsignificant paired differences therefore cannot establish clinical equivalence or fairness.

Conclusions

Within GLOBEM's 4 annual cohorts, selected connectivity features showed larger platform-associated differences than core phone behavioral features, while coverage differences also affected location. Matched transformations changed platform predictability. Because the screening models lacked demonstrated predictive usefulness, their incremental comparisons cannot establish or exclude downstream harm from platform-associated measurement differences. A shared feature name is insufficient evidence of comparable measurement. The unresolved question is which differences alter clinically useful monitoring when observation quality, owner characteristics, and device changes can be distinguished.

Acknowledgments

The authors used the Generalization of Longitudinal Behavior Modeling (GLOBEM) datasets, made available by the University of Washington and collaborating institutions through PhysioNet, and thank the original investigators for releasing this resource. The authors thank colleagues at the American University of the Middle East and the University of Wolverhampton for helpful discussions.

Data Availability

The datasets analyzed during this study are available in the PhysioNet repository (GLOBEM Dataset, version 1.1) [20]. They are not publicly available because passive-sensing data carry a risk of reidentification; access requires PhysioNet credentialing, completion of the required training, and a signed data-use agreement. Demographic variables are available only from the data custodians on special request. The analysis code and aggregate results generated during this study are included in Multimedia Appendix 2; participant-level records and predictions are not redistributed.

Abstract

Background: Health anxiety (HA), classified in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5*) under illness anxiety disorder (IAD) or somatic symptom disorder, is an increasingly prevalent condition associated with substantial psychological and health care burdens. Digital mental health interventions (DMHIs) offer scalable and accessible approaches to care, with digital behavioral interventions (DBIs), particularly internet-delivered cognitive and behavioral therapies, among the most frequently studied. However, their effectiveness in reducing HA has not been comprehensively synthesized.

Objective: This study aimed to systematically evaluate the effectiveness of DBIs for reducing HA in adults and to examine their effects on related psychological outcomes.

Methods: This systematic review and meta-analysis followed the PRISMA 2020 statement and Cochrane guidance. PubMed, Embase, Web of Science, ScienceDirect, PsycINFO, and the Cochrane Library were searched from database inception to November 1, 2025. Eligible studies included randomized controlled trials (RCTs), quasi-experimental studies, and cohort studies involving adults with HA. HA severity was the primary outcome. Random-effects meta-analyses were restricted to RCTs. Methodological quality was appraised using Joanna Briggs Institute tools, risk of bias in RCTs using Risk of Bias 2 (RoB 2), and certainty of evidence using Grading of Recommendations Assessment, Development, and Evaluation (GRADE).

Results: Sixteen studies involving 2581 participants were included, comprising 9 RCTs, 6 quasi-experimental studies, and 1 cohort study. Six RCTs involving 585 participants contributed to the primary meta-analysis. Digital interventions significantly reduced HA compared with control conditions (Hedges g=−0.77, 95% CI −1.25 to –0.30; P=.002), although between-study heterogeneity was substantial (I^2=86.7%). Leave-one-out analyses showed that this effect remained significant after exclusion of any individual trial. By contrast, pooled effects on illness-related attitudes, general anxiety, anxiety sensitivity, and depressive symptoms were not statistically significant and were characterized by substantial heterogeneity. Among the 9 RCTs, 4 were judged as having low overall risk of bias, 2 had some concerns, and 3 were at high risk. GRADE certainty was low for HA and very low for the secondary outcomes.

Conclusions: Digital interventions show potential for reducing core health-anxiety symptoms, but confidence in the magnitude and generalizability of the effect is limited by substantial heterogeneity, risk-of-bias concerns, and low certainty of evidence. Evidence for broader psychological outcomes remains inconclusive. Adequately powered, well-reported RCTs using rigorous outcome assessment, appropriate active comparators, and longer follow-up are needed to confirm effectiveness and clarify which patients benefit most and under what delivery conditions.

Trial Registration: PROSPERO CRD420251238746; https://www.crd.york.ac.uk/prospero/

KEYWORDS

health anxiety; anxiety disorder; hypochondria; digital intervention; digital behavioral intervention.

Introduction

Health anxiety (HA), classified in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)* under illness anxiety disorder (IAD) or somatic symptom disorder (SSD), is a prevalent and distressing condition characterized by persistent preoccupation with having or acquiring a serious illness despite appropriate medical reassurance, a presentation

XSL•FO
RenderX

historically referred to as hypochondriasis [1]. Although the *DSM-5* classifies these presentations under somatic symptom and related disorders, HA is widely conceptualized as part of the anxiety spectrum. It shares the core features of anxiety disorders, including excessive worry, anticipatory anxiety, and avoidance behaviors [2]. In HA, these processes are directed toward illness-related threats and manifest as fear of serious disease, hypervigilance to bodily sensations, and repeated reassurance seeking. Consistent with this overlap, HA frequently co-occurs with generalized anxiety disorder, which has an estimated lifetime prevalence of 6.2%, and may represent an early or prodromal manifestation of anxiety pathology [3]. Epidemiological evidence indicates that HA affects approximately 3.4% of the general population [4], with early UK studies reporting rates of 4%-8% [5,6], and its prevalence may reach 20% among patients attending primary care and other medical settings [7]. In the wake of recent global infectious disease outbreaks, HA has become an increasingly prominent public mental health concern [8]. The pandemic and its aftermath have also reshaped the online dissemination of health information. Compared with the general population, individuals with elevated HA are more likely to respond to such information with heightened worry, fear, and negative expectations, thereby reinforcing and worsening their symptoms [9,10]. Persistent fear of serious illness and repeated monitoring of bodily symptoms can cause substantial psychological distress and functional impairment, reducing quality of life [11]. At the system level, excessive health care use, unnecessary diagnostic testing, and productivity losses place a considerable burden on health care systems [12]. Importantly, elevated levels of HA have also been observed among health care providers [13], with prevalence rates reported to be as high as 30% in medical professionals [14]. Consequently, increasing clinical and public health attention has been directed toward these populations, highlighting the urgent need for scalable and accessible interventions to mitigate the growing impact of disease-related anxiety on public health.

A critical characteristic that must be addressed in the prevention and intervention of HA is patients' anxiety sensitivity (AS) and the involuntary emergence of negative mental imagery when processing health-related information [15]. Many individuals, driven by fear of illness, frequently search online for information about diseases and available treatments; however, excessive reliance on internet-based self-diagnosis does not alleviate anxiety and may instead exacerbate it [16]. Continuous exposure to heterogeneous and often unreliable online health information environments can further contribute to psychological dysregulation. Currently, cognitive behavioral interventions have been widely used to address disease-related anxiety at the population level [17], partially reducing anxiety sensitivity and alleviating psychological distress by optimizing daily behaviors and redirecting attentional focus. In recent years, the integration of digital technologies into behavioral therapies has emerged as a promising approach to expanding the reach of mental health services. Digital mental health interventions (DMHIs) [18], including internet-based cognitive behavioral therapy (ICBT) [19], mobile health apps [20], and digitally delivered interactive exposure therapies [21], have demonstrated efficacy comparable to face-to-face interventions in treating anxiety disorders, while offering notable advantages such as cost-effectiveness [22], anonymity, and geographic flexibility [23]. Additionally, questionnaire-based evidence suggests that improving health literacy and promoting health-related behaviors play a critical role in emotional regulation among individuals with HA [24]. Within the domain of behavioral interventions, behavioral activation (BA) has been shown to effectively reduce anxiety symptoms by disrupting avoidance cycles [25] and enhancing engagement in meaningful activities, either actively or passively [26]. When implemented through digital platforms, these behavioral strategies exhibit substantial potential for HA management by enabling continuous monitoring, remote participation, and timely support during acute health-related distress [27].

Although substantial evidence supports the effectiveness of digital interventions for general anxiety and depressive disorders, a comprehensive evaluation of digital behavioral interventions (DBIs) specifically targeting HA remains lacking. Recent reviews have provided an extensive synthesis of intervention outcomes for HA among adolescents and their parents [28], and randomized controlled trials (RCTs) have examined a range of digital technological approaches. However, the evidence remains fragmented. No systematic review has yet synthesized the overall effectiveness of DBIs for reducing HA or examined whether their effects vary across populations and study designs.

This systematic review and meta-analysis addresses these gaps by evaluating the clinical effectiveness of DBIs for individuals with HA and their effects on related psychological outcomes, including depression and stress. It also examines the emerging role of DBIs as an adjunctive approach and synthesizes evidence to inform integrated health management strategies beyond conventional cognitive behavioral therapy (CBT).

Methods

Overview

This systematic review was designed in strict accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 statement [29] (Checklist 1) and the most recent guidance of the Cochrane Handbook for Systematic Reviews of Interventions [30]. To ensure transparency and reproducibility, the review protocol was prospectively registered in the PROSPERO (International Prospective Register of Systematic Reviews; registration number CRD420251238746). The research questions were formulated using the PICOS (Population, Intervention, Comparator, Outcomes, and Study design) framework [31], which provided a structured approach to clearly define the scope and focus of the review and to ensure comprehensive and systematic coverage of the topic.

Eligibility Criteria

Inclusion Criteria

Inclusion Criteria: (1) The study designs included RCTs, quasi-experimental studies (QESs), and cohort studies (CSs). Both controlled (ie, with a separate comparator group) and uncontrolled single-arm pre-post designs were considered

XSL•FO
RenderX

eligible for inclusion. All studies were required to provide original outcome data and complete procedural descriptions; (2) the participants meeting diagnostic criteria for HA, including DSM-IV hypochondriasis, *DSM-5* SSD with predominant HA features, or IAD, or participants with elevated HA confirmed using validated scales (eg, HAI ≥30, SHAI ≥18, WI-7 >14). Studies were eligible when HA was assessed as a primary target outcome; (3) digital health interventions targeting HA, defined as structured psychological interventions delivered wholly or mainly through digital technology. Eligible approaches included internet-based CBT (guided or unguided), internet-based ACT, cognitive bias modification, and other digital self-help programs, delivered via web-based platforms, mobile apps, e-books or bibliotherapy, video programs, or interactive formats such as chatbots and serious games. Comparators included waitlist, psychoeducation, usual care, or face-to-face therapy; (4) primary outcomes: severity of HA assessed using validated instruments (eg, HAI, SHAI, and Illness Attitude Scales [IASs]). Secondary outcomes: comorbid symptoms (depression and generalized anxiety), functional impairment (Sheehan Disability Scale [SDS] and World Health Organization Disability Assessment Schedule II [WHODAS-II]), quality of life, and treatment adherence/satisfaction; (5) peer-reviewed original articles published in English or Chinese, from database inception to November 1, 2025.

Exclusion Criteria

(1) Noninterventional studies (cross-sectional studies, retrospective analyses, reviews, meta-analyses), no clear definition of groups without sufficient outcome data, duplicate publications, or studies with overlapping data; (2) Studies involving minors or participants without confirmed HA (no DSM diagnosis or subclinical scale scores), or participants with severe psychiatric comorbidities, including psychotic disorders, bipolar disorder, acute suicidal ideation or behavior, or substance use disorders (active within the past 6 months). Studies were also excluded if participants had severe physical illnesses requiring urgent medical intervention or unstable medication use (antidepressants or anxiolytics adjusted within 2 months), or if concurrent psychotherapy targeting HA (eg, face-to-face CBT) was provided during the study period; (3) Intervention types: nondigital interventions (eg, behavioral therapies without digital components or pharmacotherapy alone), or interventions with unclear core components or implementation procedures; (4) Outcomes: absence of primary outcomes related to HA or IAD, incomplete or nonextractable data, or outcome measures lacking psychometric validation; (5) Non-peer-reviewed literature, including conference abstracts, dissertations, and gray literature.

Electronic Databases and Search Strategy

This review aimed to identify studies examining the effects of digital therapeutics (DTs) and digitally assisted behavioral therapies on the mental health outcomes of individuals with HA. Systematic searches were conducted in PubMed, Embase, Web of Science, ScienceDirect, PsycINFO, and the Cochrane Library from database inception to November 1, 2025. The primary search terms for the research question included health anxiety and illness anxiety (ie, “health anxiety” [All Fields] OR “hypochondriasis” [MeSH] OR “hypochondria” [All Fields]). Intervention-related terms included DT, behavioral activation (BA), and DBIs. Gray literature was explicitly excluded (Table 1). The search strategy was independently implemented by 2 reviewers, who initially screened titles and abstracts. To avoid duplication, all retrieved records were imported into the Zotero reference management software [32]. In addition to database searches, supplementary strategies were applied, including snowballing of reference lists, to enhance the comprehensiveness and depth of retrieval. In accordance with the PRISMA guidelines [33], this review primarily included RCTs, supplemented by QES and CS, to systematically evaluate the effectiveness and mechanisms of digital interventions for HA in adults. Highly similar or overlapping studies were excluded (details in Multimedia Appendix 1), and reference lists of relevant prior reviews were also screened to ensure comprehensive inclusion.

Selection of Studies

Duplicate records were systematically identified and removed using Zotero. Following deduplication, all unique records underwent a structured screening process conducted by 2 reviewers. Records that were clearly unrelated to the scope of the review were initially excluded on the basis of their titles. Subsequently, the remaining publications were assessed using their titles, abstracts, and keywords. At this point, any record considered potentially relevant by at least one reviewer, or for which eligibility remained uncertain, was retained for full-text assessment.

The full texts of these potentially eligible reports were then examined in detail against the predefined inclusion and exclusion criteria. In particular, eligibility was determined according to the types of anxiety addressed, the forms and characteristics of the interventions, and the measurement scales used to evaluate the core outcomes. During this process, JX sequentially assessed each article to determine whether it met the eligibility requirements for inclusion. Where disagreements concerning full-text inclusion arose, they were resolved through discussion. However, when consensus could not be reached, GH and JW made the final decision. Overall, this sequential screening procedure enabled the systematic identification and evaluation of relevant studies, while the complete study selection process was documented and reported in accordance with the PRISMA guidelines.

Data Extraction

This review used a structured PICOS-based approach for preliminary data extraction from the included studies. Data were extracted independently by 3 reviewers. Approximately 30% of the extracted data were randomly selected and cross-checked by a fourth reviewer to assess consistency and accuracy. This multireviewer extraction and random verification process was used to assess the reliability of the extracted data. A standardized Excel-based extraction form was developed by the research team based on the PICOS framework to systematically collect core study information.

XSL•FO
RenderX

Population (P): individuals diagnosed with hypochondriasis or IAD, as well as individuals exhibiting moderate levels of HA.

Intervention (I): specific categories of DBIs, alongside detailed descriptions of their implementation, as well as forms of intervention deliverable via the internet.

Comparator (C): characteristics and descriptions of control or comparison interventions.

Outcomes (O): the primary outcome must be directly related to HA, while secondary outcome measures include, but are not limited to, other functional impairments resulting from health anxiety, as well as treatment adherence and satisfaction.

Study design (S): study type, including RCTs, QES, or CS.

Additionally, during the data extraction process, if any information was unclear or missing, the research team attempted to contact the original authors for additional data to ensure the completeness of extracted information. All extracted data were systematically organized in a standardized Excel sheet for subsequent quality assessment, data synthesis, and analysis to ensure data reliability and consistency.

Statistical Analysis

When studies were sufficiently comparable in terms of interventions, outcomes, and study designs, quantitative synthesis was undertaken. Following Cochrane methodological guidance, multiple reports of the same trial, including secondary analyses, were linked and treated as a single study [34]. When reports provided overlapping data for the same comparison, outcome, and time point, data from the primary trial report were preferentially used. Secondary reports were consulted to supplement eligible data unavailable in the primary report. Each participant was counted only once within each outcome-specific meta-analysis. All analyses were performed using custom-written code in Python (version 3.12; Python Software Foundation) [35]. For each eligible intervention–control comparison, we extracted postintervention means, SDs, and analyzed sample sizes for both groups. End point values were used consistently, as both end point and change scores are acceptable for continuous-outcome meta-analysis when appropriately analyzed [30].

The effect measure was selected according to the outcome construct and measurement scale. Health-anxiety outcomes assessed using different instruments or different versions of the same instrument, including the Health Anxiety Inventory (HAI) and its short form, the Short Health Anxiety Inventory (SHAI), were pooled using standardized mean differences (SMDs), because these measures assess the same underlying construct but have different scoring ranges [30,36]. SMDs were estimated as Hedges *g*, which applies a small-sample correction to Cohen *d* at the comparison level [37]. Mean differences (MDs) were used when the same outcome was assessed using the same instrument and scoring metric. Score directions were harmonized before analysis. Other prespecified outcomes, including illness attitudes, general anxiety, anxiety sensitivity, and depressive symptoms, were analyzed separately and were not combined with the primary health-anxiety outcome.

For comparison , the MD and its sampling variance were calculated as follows:

MDi=X¯I,i−X¯C,i

VMD,i=SDI,i2nI,i+SDC,i2nC,i

For SMD analyses, the pooled SD across the 2 groups, Hedges *g*, and its sampling variance were calculated using the RevMan algorithm as follows [38]:

SDp,i=(nI,i−1)SI,i2+(nC,i−1)SC,i2nI,i+nC,i−2

gi=|1−34(nI,i+nC,i)−9X˙I,i−X˙C,iSDp,i|

Vg,i=nI,i+nC,inI,inC,i+gi22(nI,i+nC,i−3.94)

Here, and *C* denote the digital intervention and control groups, respectively; ¯, , and *n* denote the postintervention mean (SD), and number of participants analyzed; and , and , denote the corresponding sampling variances. Before pooling, all outcome scales were oriented so that lower scores represented better outcomes; consequently, negative effect estimates indicated effects favoring the digital intervention.

Because the underlying intervention effects were expected to vary across populations, intervention formats, treatment durations, and comparator conditions, an inverse-variance random-effects model was prespecified [38,39]. The between-study variance was estimated using the DerSimonian–Laird method, and the random-effects weight assigned to comparison *i* was calculated as

wi=1Vi+τ2

where $_i$ denotes the sampling variance of the corresponding MD or SMD. Pooled effects were reported with 2-sided Wald 95% CIs, and <.05 was considered statistically significant. Model selection was not based on an ^{2} threshold, because current guidance recommends selecting the statistical model according to assumptions about the underlying effects rather than solely according to a statistical test or threshold for heterogeneity [38].

Robustness was examined using a leave-one-out sensitivity analysis. Within each outcome meta-analysis, each eligible trial-specific comparison was omitted in turn, and the random-effects meta-analysis was refitted using the remaining comparisons. The pooled effect, 95% CI, ^ 2, Cochran , 2 and comparison weights were recalculated after each omission. A trial-specific comparison was considered potentially influential if its omission materially changed the magnitude or direction of the pooled effect, caused the CI to cross the null value, or substantially altered the estimated heterogeneity [40].

Quality Appraisal of the Included Studies

The methodological quality of the included studies was appraised with the Joanna Briggs Institute (JBI) critical appraisal checklists matched to each study design [41]. The 13-item checklist for RCTs covers randomization and allocation concealment, baseline comparability, blinding of participants, treatment providers, and outcome assessors, equal treatment of the groups apart from the intervention, completeness of follow-up, analysis in the randomized groups, consistent and reliable outcome measurement, and appropriate statistical analysis and trial design. The 9-item checklist for QESs

XSL•FO
RenderX

addresses clarity of the cause-and-effect relationship, the presence of a control group, comparability of participants and of the care they received, repeated pre- and postintervention measurements, consistent and reliable outcome measurement, completeness of follow-up, and appropriate statistical analysis. The 11-item checklist for CSs addresses similarity and recruitment of the comparison groups, valid and reliable exposure measurement, identification and handling of confounders, absence of the outcome at baseline, valid and reliable outcome measurement, duration and completeness of follow-up, and appropriate statistical analysis. Following thresholds commonly applied in previous systematic reviews [42] using the JBI checklists, studies meeting ≥70% of applicable items were rated high quality, 50% - 69% moderate, and <50% as low quality. For fully applicable checklists, these correspond to total scores of 10 - 13, 7 - 9, and ≤6 (RCTs); 7 - 9, 5 - 6, and ≤4 (quasi-experimental); and 8 - 11, 6 - 7, and ≤5 (Cohort). The full wording of each item is given in the footnotes to Table 2. Each item was rated as yes, no, unclear, or not applicable. One point was assigned for each yes response and zero points; otherwise, items rated not applicable were excluded from the denominator, and overall quality was expressed as the percentage of applicable items meeting the criteria. Item-level ratings, total scores, and overall classifications for all 16 studies are presented in Table 2. Two reviewers (JX and JS) performed the appraisal independently, interrater agreement was quantified with Cohen kappa, and disagreements were resolved through discussion with a third reviewer (JW). No study was excluded on the basis of its quality rating [43]. The risk of bias of the RCTs and the certainty of the pooled evidence were further assessed.

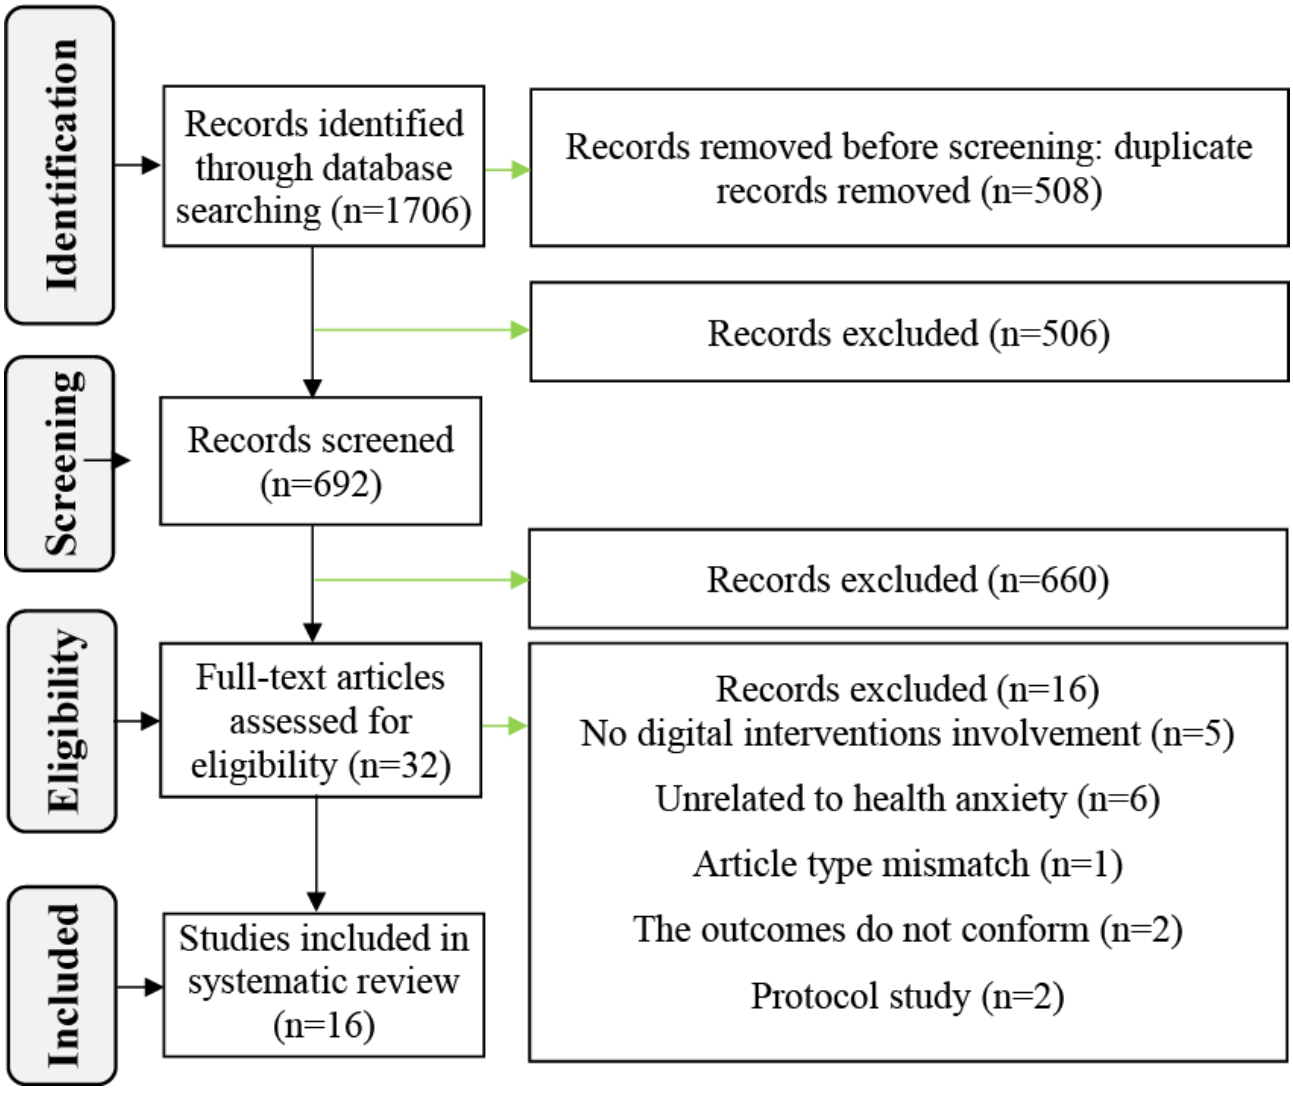
Quality Assessment of Evidence and Risk of Bias

The risk of bias of the included RCTs was assessed with the revised Cochrane Risk of Bias 2 tool for randomized trials (RoB 2) [60]. The tool covers 5 domains. These are bias arising from the randomization process, bias due to deviations from intended interventions, bias due to missing outcome data, bias in measurement of the outcome, and bias in selection of the reported result. Each domain was judged as low risk of bias, some concerns, or high risk of bias. Because RoB 2 is applied to a specific result rather than to a trial as a whole, the assessment addressed the primary outcome of this review, namely HA symptoms at postintervention as measured with the HAI, the SHAI, or the IADs in each trial. An overall judgment was then derived for each trial following the RoB 2 algorithm. A trial was rated as having a low risk when all 5 domains were judged low risk, as some concerns when at least one domain raised some concerns without any high risk judgment, and as high risk when any domain was judged high risk or when several domains raised some concerns to a degree that substantially reduced confidence in the result. Two reviewers independently conducted all assessments in accordance with the Cochrane Handbook for Systematic Reviews of Interventions, and disagreements were resolved through discussion or consultation

XSL•FO
RenderX

with a third reviewer. The methodological quality of quasi-experimental and CSs was appraised with the JBI checklists, as described in section "Quality Appraisal of the Included Studies."



Result

Search Results and Study Characteristics

Overview

A comprehensive search was conducted across 6 electronic databases (PubMed, Embase, Web of Science, ScienceDirect, PsycINFO, and the Cochrane Central Register of Controlled Trials [CENTRAL]). A total of 1706 records were identified through the database searches. After 508 duplicate records were removed, 1198 unique records remained. Title screening excluded 506 records, leaving 692 records for abstract screening. Of these, 660 records were excluded, and the full texts of 32 articles were assessed for eligibility. Sixteen full-text articles were subsequently excluded because they involved nondigital interventions (n=6), did not target HA (n=5), had an ineligible article type (n=1), did not report eligible outcome measures (n=2), or were study protocols (n=2). Ultimately, 16 studies met the predefined eligibility criteria and were included in the systematic review. The study-selection process is presented in Figure 1.

Figure 1. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram for the included and excluded articles.

The 16 included studies were published between 2011 and 2025 and comprised 9 RCTs, 6 QESs, and one CS. Five studies were conducted in Sweden [44,45,47,52,59], 4 in Denmark [49,53,57,58], 3 in Australia [46,48,55], and 1 each in New Zealand [56], China [50], Japan [54], and the United States [51]. A total of 2581 participants were included, with individual study sample sizes ranging from 4 to 904. Intervention duration was most commonly 12 weeks (n=10) [44-49,52,57-59]. The remaining interventions comprised an 8-week program (n=1) [58], a single-session lasting 12 minutes (n=1) [54], a 14-day chatbot program (n=1) [56], a 12-day intervention (n=1) [50], a 1-week computerized intervention (n=1) [51], and a flexible program that allowed participants up to 90 days for completion (n=1) [55]. By study design, the evidence base included RCTs (n=9) [44-52], QESs (n=6) [53-58] and one CS (n=1) [59]. Study populations included adults with SSD/IAD or hypochondriasis (n=4) [44,51,52,59], severe HA (n=5) [29,45,46,52,57], HA without a specific diagnostic label (n=4) [47,50,55,56],

XSL•FO
RenderX

COVID-19-related HA (n=1) [58], HA with cyberchondria (n=1) [48], and HA associated with inflammatory bowel disease (n=1) [54], as well as parents with HA by proxy (n=1) [53]. These population categories were not mutually exclusive.

Delivery mode and intervention approach were considered separately. Regarding delivery support, guided digital interventions were evaluated in 11 studies, whereas unguided interventions were evaluated in 6 studies. One study included both guided and unguided intervention arms. Therefore, these categories were not mutually exclusive. Regarding intervention approach, 8 studies evaluated internet-delivered CBT, including exposure-based CBT. Three studies evaluated internet-delivered acceptance and commitment therapy. One study each evaluated an integrated CBT and acceptance and commitment therapy (ACT) program, a CBT-based chatbot, internet-based cognitive bias modification of interpretations, a video-testimonial intervention, and a brief computerized intervention combining psychoeducation with interpretation-bias modification.

The primary or co-primary outcomes across the included studies included core HA, illness-related attitudes, generalized anxiety, anxiety sensitivity, and depressive symptoms. Core HA was most commonly assessed using the SHAI (n=8) [45,46,48,50,51,55,56,59] and the HAI (n=4) [44,45,47,52]. Illness-related attitudes were assessed using the IAS (n=4) [44,45,47,52], generalized anxiety using the Beck Anxiety Inventory (BAI; n=4) [44,45,47,52], anxiety sensitivity using the Anxiety Sensitivity Index (ASI; n=4) [44,45,47,52], and depressive symptoms using the Montgomery–Åsberg Depression Rating Scale–Self-report (MADRS-S; n=5) [44,45,47,52,59]. Because several studies assessed more than one primary or co-primary outcome, these categories were not mutually exclusive. Detailed outcome measures and study characteristics are presented in Multimedia Appendix 2.

JBI Critical Appraisal Checklist for RCT

The methodological quality of the included randomized controlled trials was assessed using the JBI Critical Appraisal Checklist for Randomized Controlled Trials, which comprises 13 items addressing randomization, allocation concealment, blinding, group comparability, follow-up, outcome measurement, statistical analysis, and trial design. (1) Was true randomization used for assignment of participants to treatment groups? (2) Was allocation to treatment groups concealed? (3) Were treatment groups similar at the baseline? (4) Were participants blind to treatment assignment? (5) Were those delivering treatment blind to treatment assignment? (6) Were outcomes assessors blind to treatment assignment? (7) Were treatment groups treated identically other than the intervention of interest? (8) Was follow-up complete and if not, were differences between groups in terms of their follow-up adequately described and analyzed? (9) Were participants analyzed in the groups to which they were randomized? (10) Were outcomes measured in the same way for treatment groups? (11) Were outcomes measured in a reliable way? (12) Was appropriate statistical analysis used? (13) Was the trial design appropriate, and any deviations from the standard RCT design (individual randomization, parallel groups) accounted for in the conduct and analysis of the trial?

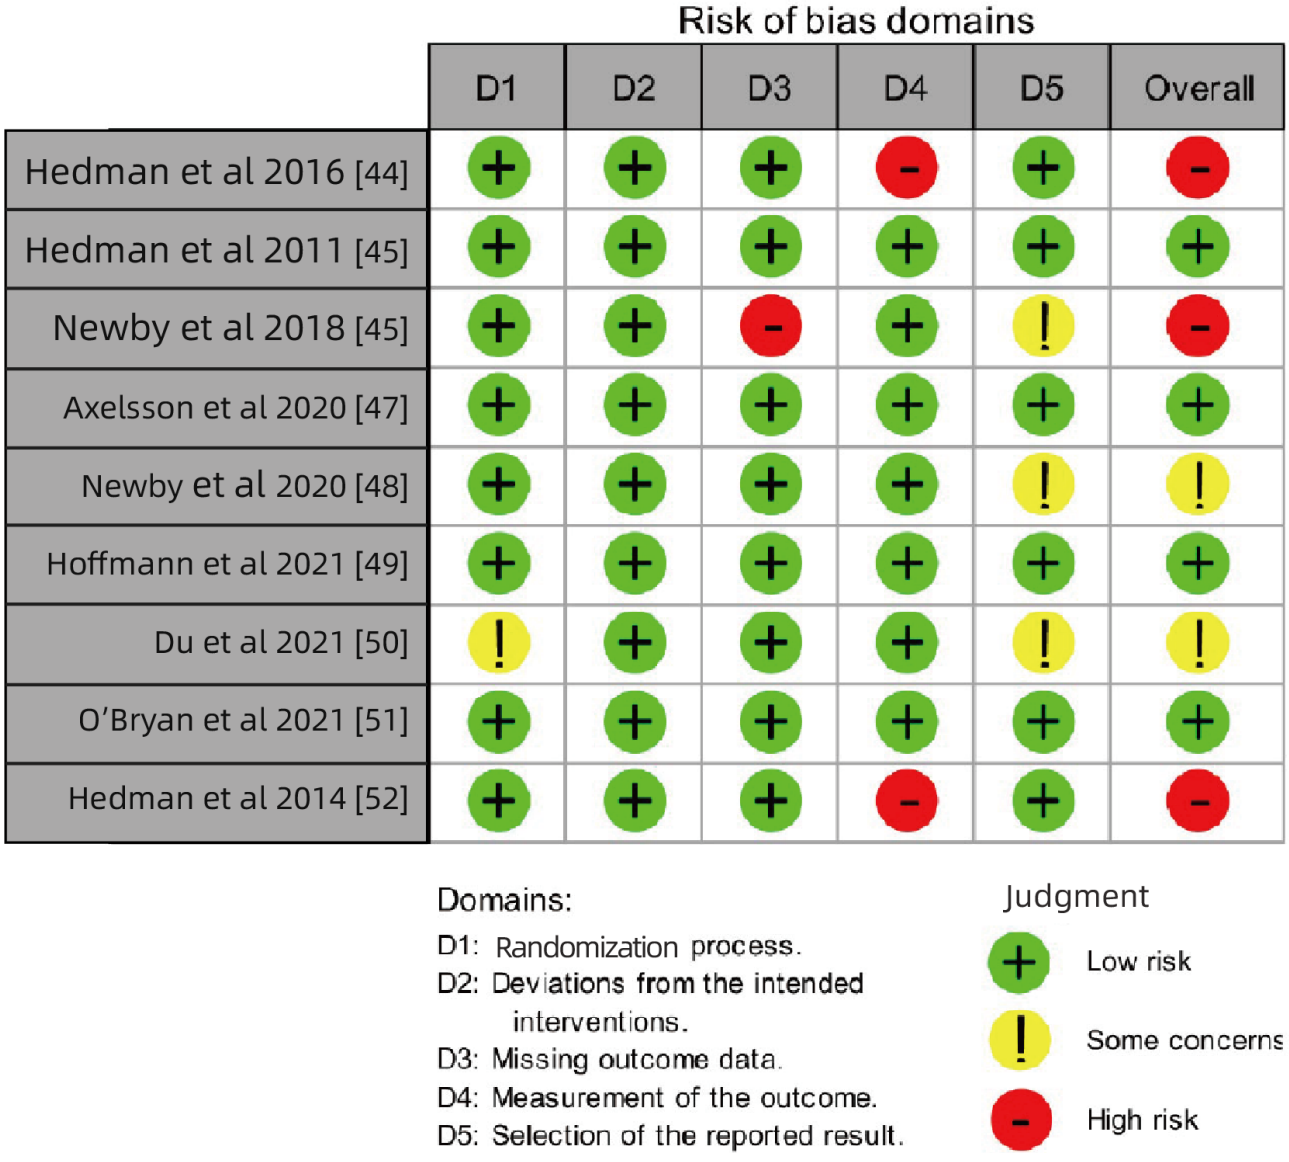
JBI Critical Appraisal Checklist for QESs

The JBI critical appraisal checklist for QESs consists of the following questions: (1) Is it clear in the study what the “cause” is and what the “effect” is (ie, there is no confusion about which variable comes first)? (2) Was there a control group? (3) Were participants included in any comparisons similar? (4) Were the participants included in any comparisons receiving similar treatment/care, other than the exposure or intervention of interest? (5) Were there multiple measurements of the outcome, both pre and post the intervention/exposure? (6) Were the outcomes of participants included in any comparisons measured in the same way? (7) Were outcomes measured in a reliable way? (8) Was follow-up complete and if not, were differences between groups in terms of their follow-up adequately described and analyzed? (9) Was appropriate statistical analysis used?

JBI Critical Appraisal Checklist for CSs

The JBI critical appraisal checklist for CSs consists of the following questions: (1) Were the 2 groups similar and recruited from the same population? (2) Were the exposures measured similarly to assign people to both exposed and unexposed groups? (3) Was the exposure measured in a valid and reliable way? (4) Were confounding factors identified? (5) Were strategies to deal with confounding factors stated? (6) Were the groups/participants free of the outcome at the start of the study (or at the moment of exposure)? (7) Were the outcomes measured in a valid and reliable way? (8) Was the follow-up time reported and sufficient to be long enough for outcomes to occur? (9) Was follow-up complete, and if not, were the reasons for loss to follow-up described and explored? (10) Were strategies to address incomplete follow-up used? (11) Was appropriate statistical analysis used?

Methodological Quality and Risk of Bias



Two reviewers independently assessed the quality of the included studies (see Table 2), and the results showed an interrater agreement of 87.58% (κ=0.81). The 9 RCTs achieved total scores of 10 to 11, and all were classified as high quality. The trials by Hedman et al [45], Newby et al [46], and Hoffmann et al [49] received the highest score of 11, while the remaining studies each scored 10 [44,47,48,50-52]. Across individual assessment domains, RCTs generally demonstrated strong methodological performance in terms of randomization, baseline comparability, completeness of follow-up, consistency and reliability of outcome measurement, and appropriateness of study design. The principal weakness concerned blinding: participants were blinded in 22% of trials, reflecting the inherent difficulty of blinding in digital intervention research. Most studies implemented blinding only at specific stages rather than across the entire trial process. For QES, all 6 studies [53-58] achieved favorable quality scores, meeting high-quality standards regarding causal clarity, participant comparability, consistency and reliability of outcome measurement, and appropriateness of statistical analyses. Nonetheless, incomplete data reporting and lack of a control group remained common limitations. Quality assessment of the single CS [59] rated it as high quality (8 of 9 applicable items); items 1 and 2 were not applicable because a single treated cohort was enrolled without

XSL•FO
RenderX

an unexposed comparison group and follow-up was incomplete, which should be considered when interpreting its findings.

This review focused on HA outcomes and assessed all included RCTs using 5 criteria of the Cochrane Collaboration risk-of-bias assessment tool [61]. Of the 16 included studies, the 9 RCTs were assessed for the HA outcome using the 5-domain Cochrane RoB 2 tool (Figure 2). Overall, 4 trials were rated as having a low risk of bias, 2 as having some concerns, and 3 as having a high risk of bias. For the randomization process (D1), 8 trials were rated as low risk and one as having some concerns. All 9 trials were rated as low risk for deviations from intended interventions (D2). For missing outcome data (D3), 8 trials were rated as low risk and one as high risk. For measurement of the outcome (D4), 7 trials were rated as low risk and 2 as high risk. For selection of the reported result (D5), 6 trials were rated as low risk and 3 as having some concerns. High-risk judgments were recorded for Newby et al [46] in D3 and for Hedman et al [44] and Hedman et al [52] in D4. Some concerns were identified for Du et al [50] in D1 and for Newby et al [46], Newby and McElroy [48], and Du et al [50] in D5. Newby et al [46] were judged to be at high risk in D3 because 16 of 102 randomized participants were excluded before baseline assessment and only 69 provided posttreatment data. The authors also acknowledged that the outcomes of participants with missing data were unknown and that treatment effects might therefore have been overestimated. Hedman et al [44] was rated as having a high risk of bias in D4 because the primary outcome was assessed using an unblinded, participant-reported measure, and comparison with a waiting-list control could have influenced symptom reporting. The D4 judgment for Hedman et al [52] was similarly based on the use of an unblinded self-reported HA measure, although both groups received active interventions with comparable treatment credibility.

Figure 2. Cochrane risk of bias ratings for included randomized controlled trials (n=9) [44-52].

Results of Meta-Analysis

All 6 meta-analyses reported in this section were restricted to RCTs. The 3 quasi-experimental trials, the single CS, and the replicated single-case experimental design are summarized narratively in Table 3 and were not pooled with the RCT effect estimates. All outcomes were synthesized using prespecified random-effects models with the DerSimonian-Laird estimator

XSL•FO
RenderX

(Figure 3). Because HA was measured using both the 64-item HAI (HAI-64 [44,45,52]) and the 18-item SHAI (SHAI-18 [46,50,51]), posttreatment effects were standardized and pooled using Hedges *g*. Across 6 trials involving 585 participants, digital interventions produced a statistically significant, moderate-to-large reduction in HA relative to control conditions (Hedges g=–0.77; 95% CI –1.25 to –0.30; z=–3.17; P=.002) [44-46,50-52]. All trial-level point estimates favored digital interventions and ranged from –1.60 to –0.21, although the CIs of 3 individual trials included zero. Considerable between-trial heterogeneity was observed (τ^2=0.30; Q_5=37.55; P<.001; I^2=86.7%) indicating substantial variation in the magnitude of the intervention effects.

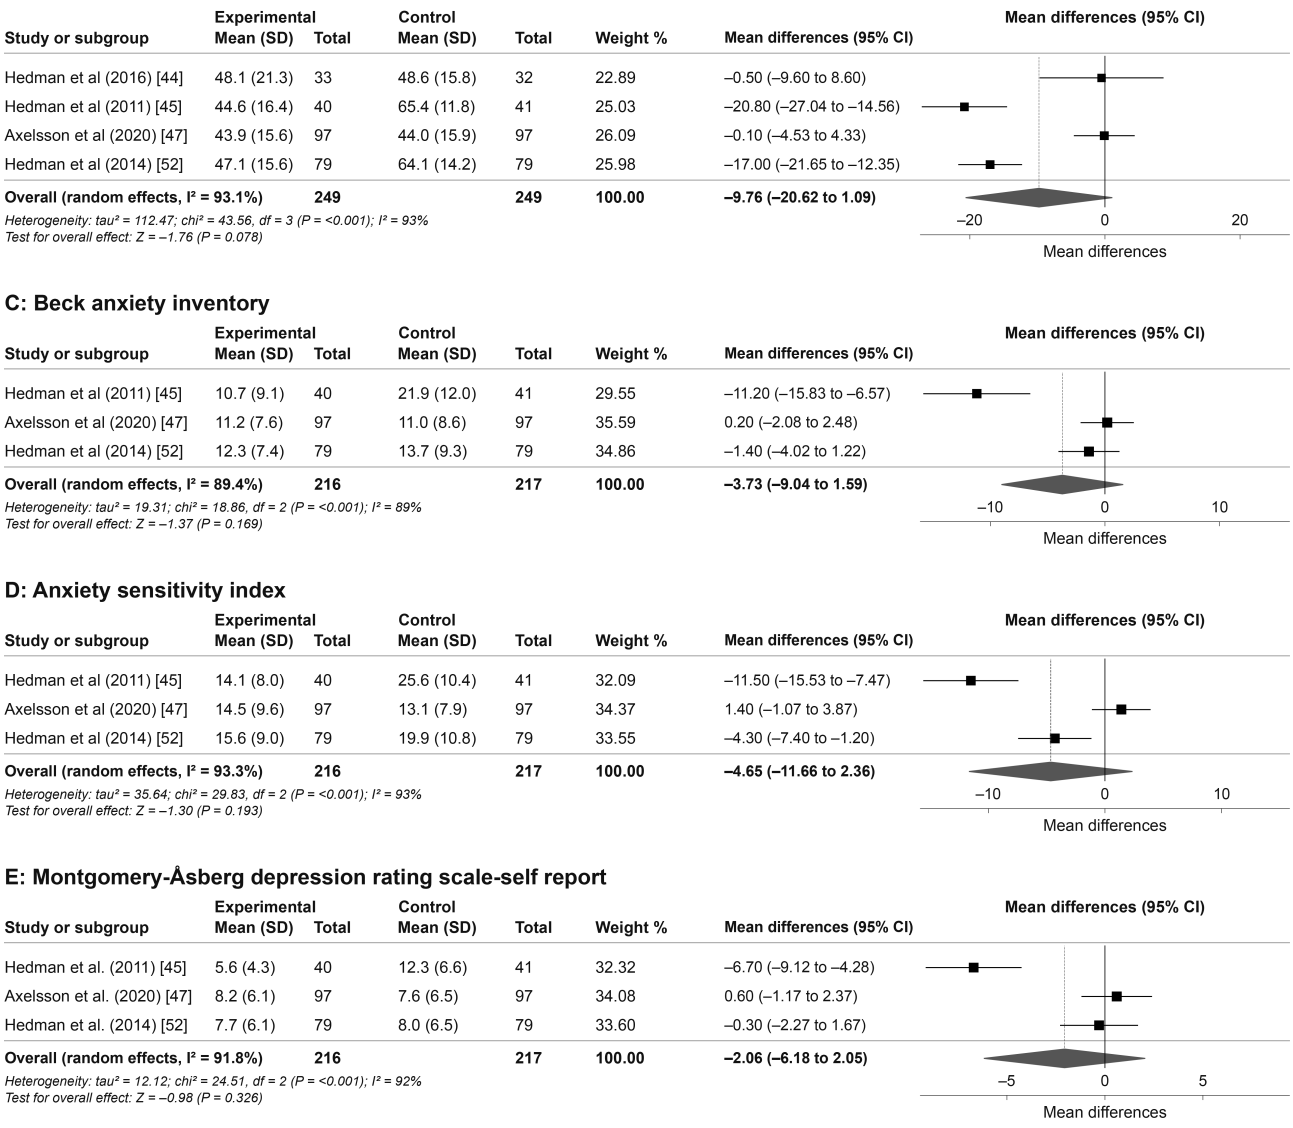

Figure 3. Effects of digital behavior interventions for health anxiety outcomes (standardized mean differences [SMDs]) [44-46,50-52].

For outcomes assessed using the same measurement instrument, mean differences (MDs) were pooled. Four trials involving 498 participants assessed illness-related attitudes using the IAS (Figure 4). Although the pooled estimate favored digital interventions, the effect was not statistically significant (MD –9.76, 95% CI –20.62 to 1.09; z=–1.76; *P*=.08) [44,45,47,52]. Similarly, no statistically significant posttreatment effect was observed for general anxiety measured using the Beck Anxiety Inventory (BAI; 3 trials, n=433; MD –3.73, 95% CI –9.04 to 1.59; z=–1.37; *P*=.17) [44,45,47,52]. Anxiety sensitivity measured using the ASI (3 trials, n=433) also did not differ significantly between digital interventions and control conditions (MD –4.65, 95% CI –11.66 to 2.36; z=–1.30; *P*=.20) [45,47,52]. Likewise, the pooled effect on depressive symptoms measured using the MADRS-S (3 trials, n=433) was not statistically significant (MD –2.06, 95% CI –6.18 to 2.05; z=-0.98; *P*=.33) [45,47,52]. Thus, although all pooled point estimates were in the direction of lower symptom scores following digital interventions, the corresponding CIs included zero.

XSL•FO
RenderX

Figure 4. Effects of digital behavioral interventions on secondary psychological outcomes (mean differences [MDs]) [44,45,47,52].

Note: pre-specified random effects (DerSimonian-Laird) model used for all outcomes.

Substantial heterogeneity was present for the IAS: τ^2=112.47; Q_3=43.56; P<.001; I^2=93.1% [44,45,47,52], BAI: τ^2=19.31; Q_2=18.86; P<.001; I^2=89.4% [45,47,52], ASI: τ^2=35.64; Q_2=29.83; P<.001; I^2=93.3% [45,47,52], and MADRS-S: τ^2=12.12; Q_2=24.51; P<.001; I^2=91.8% [45,47,52].

Leave-one-out sensitivity analyses were performed by sequentially removing each trial and recalculating the pooled effects using the same random-effects model. For the primary health-anxiety outcome, the pooled effect remained statistically significant after the exclusion of any individual trial. The recalculated effect sizes ranged from Hedges g=–0.90 to Hedges g=–0.60, and all 95% CIs excluded zero, supporting the robustness of the overall treatment effect [44-46,50-52]. The smallest pooled effect was obtained after excluding the trial by Hedman et al [45], Hedges g=–0.60, 95% CI –1.02 to –0.18, whereas the largest effect was obtained after excluding the trial by Du et al [50], Hedges g=–0.90, 95% CI –1.46 to –0.34. However, heterogeneity remained substantial across all leave-one-out iterations, with I^2 values ranging from 80.4% to 88.9%, indicating that no single trial fully explained the observed between-trial variability.

The sensitivity analyses produced less stable findings for some secondary outcomes. For the IAS, leave-one-out estimates ranged from MD –13.44 to MD –6.08, with I^2 values ranging from 85.3% to 94.9%. The pooled effect generally remained nonsignificant; however, after the exclusion of the trial by Axelsson et al [47], the effect became statistically significant, MD –13.44, 95% CI –23.14 to –3.74; I^2=85.3%. This result indicates that the pooled IAS finding was sensitive to the inclusion of the Axelsson et al [47] trial, although substantial residual heterogeneity remained.

For the BAI, all leave-one-out estimates remained statistically nonsignificant and ranged from MD –6.11 to MD –0.49, supporting the stability of the primary null finding [45,47,52]. Notably, excluding the trial by Hedman et al [45] reduced the pooled effect to MD –0.49, 95% CI –2.21 to 1.23, and eliminated the observed heterogeneity, I^2=0%. In contrast, heterogeneity remained high when either the Axelsson et al [47]

XSL•FO
RenderX

or Hedman et al [52] trial was excluded, I^2=92.3% and 94.7%, respectively. These findings suggest that the Hedman et al [45] trial accounted for a substantial proportion of the heterogeneity in the BAI analysis.

For the ASI, leave-one-out estimates ranged from MD −7.78 to MD −1.37, with residual heterogeneity remaining substantial in all analyses, I^2=87.0% - 96.5% [45,47,52]. Exclusion of the Axelsson et al [47] trial resulted in a statistically significant pooled effect, MD –7.78, 95% CI –14.83 to –0.73; I^2=87.0%, whereas the effect remained nonsignificant following the exclusion of either the Hedman et al [45] or Hedman et al [52] trial. Therefore, similar to the IAS finding, the ASI result was sensitive to the inclusion of the Axelsson et al [47] trial.

For the MADRS-S, the pooled estimates remained nonsignificant regardless of which trial was removed and ranged from MD –3.46 to MD 0.20 [45,47,52]. Excluding the trial by Hedman et al [45] shifted the pooled estimate toward the null, MD 0.20, 95% CI –1.12 to 1.51, and reduced heterogeneity from I^2=91.8% to 0%. By comparison, heterogeneity remained high after excluding the Axelsson et al [47] or Hedman et al [52] trial, I^2=93.8% and 95.6%, respectively. This pattern suggests that the Hedman et al [45] trial exerted a substantial influence on both the direction of the pooled MADRS-S estimate and the observed heterogeneity, although its exclusion did not alter the conclusion regarding statistical nonsignificance.

Overall, the leave-one-out analyses supported the robustness of the significant posttreatment effect on HA and the nonsignificant findings for the BAI and MADRS-S. In contrast, the IAS and ASI findings were less stable because the exclusion of the Axelsson et al [47] trial changed their pooled effects from nonsignificant to statistically significant. These secondary-outcome results should therefore be interpreted cautiously, particularly given the small number of contributing trials and the persistently high heterogeneity.

Although the consistently high values indicated marked between-trial heterogeneity, they should not be interpreted as evidence of moderation. No formal subgroup-difference tests or meta-regression analyses were conducted. Differences in scoring metrics between the HAI-64 and SHAI-18 were addressed by pooling standardized effect estimates, whereas the leave-one-out analyses evaluated the influence of individual trials; neither procedure constituted a moderator analysis.

Grading of Recommendations Assessment, Development, and Evaluation Assessment

This study used the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) approach to assess the certainty of evidence from the meta-analysis results (Table 4). Overall, the certainty of evidence for the 5 outcomes ranged from low to very low, and all 5 outcomes were informed exclusively by RCTs. Specifically, the meta-analysis of 6 RCTs regarding HA was rated as low-certainty evidence. Although the pooled estimate favored the intervention and the 95% CI did not include the null value, so that the estimate was not downgraded for imprecision, the rating was lowered because of risk-of-bias concerns across the included trials and substantial unexplained heterogeneity (I^2=86.7%). The meta-analysis for illness attitudes (IAS) was based on 4 RCTs and was rated as very low-certainty evidence, owing to risk-of-bias concerns, materially different point estimates across trials with considerable heterogeneity, and imprecision of the pooled estimate. General anxiety symptoms (BAI), anxiety sensitivity (ASI), and depressive symptoms (MADRS-S) were each assessed on the basis of 3 RCTs, and each was rated as very low-certainty evidence for the same 3 reasons: risk of bias, inconsistency, and imprecision, with the 95% CI in each case including both no effect and a potentially important benefit. No outcome was downgraded for indirectness, and publication bias was not formally assessed because fewer than 10 trials contributed to each outcome. Overall, the GRADE assessment indicates that the current evidence for digital interventions in HA remains limited. Although the pooled estimate for health anxiety favored the intervention, confidence in the effects across outcomes is constrained by methodological limitations of the contributing trials, between-study heterogeneity, and limited precision. Overall, the available evidence suggests that digital interventions may reduce HA symptoms; however, substantial uncertainty remains regarding the magnitude of the true effect and their effects on other psychological outcomes.

XSL•FO
RenderX

Table . GRADE[a] assessment of the certainty of evidence for the effects of digital interventions for health anxiety compared with control conditions.

Outcome	Number of studies	Study design	Risk of bias	Inconsistency	Indirectness	Imprecision	Publication bias	Participants, intervention/control (n)	Effect estimate (95% CI)	Certainty
Health Anxiety Inventory	6	Randomized trials	Serious[b]	Serious[c]	Not serious[d]	Not serious[e]	Undetected[f]	293/292 (n=585)	Hedges *g*=–0.77 (–1.25 to –0.30)	Low
Illness Attitude Scales	4	Randomized trials	Serious[b]	Serious[g]	Not serious[d]	Serious[h]	Undetected[f]	249/249 (n=498)	MD[i]=–9.76 (–20.62 to 1.09)	Very low
Beck Anxiety Inventory	3	Randomized trials	Serious[j]	Serious[g]	Not serious[d]	Serious[h]	Undetected[f]	216/217 (n=433)	MD=–3.73 (–9.04 to 1.59)	Very low
Anxiety Sensitivity Index	3	Randomized trials	Serious[j]	Serious[g]	Not serious[d]	Serious[h]	Undetected[f]	216/217 (n=433)	MD=–4.65 (–11.66 to 2.36)	Very low
Montgomery-Åsberg Depression Rating Scale-Self report	3	Randomized trials	Serious[j]	Serious[g]	Not serious[d]	Serious[h]	Undetected[f]	216/217 (n=433)	MD=–2.06 (–6.18 to 2.05)	Very low

[a]GRADE: Grading of Recommendations Assessment, Development, and Evaluation.

[b]Downgraded one level for risk of bias because a substantial proportion of the evidence was contributed by studies rated as high risk or having some concerns in the overall Risk of Bias 2 assessment.

[c]Downgraded one level for inconsistency because of substantial unexplained heterogeneity (I^2=86.7%), although the direction of effect was generally consistent.

[d]Not downgraded for indirectness because the populations, interventions, comparators, and outcomes were considered consistent with the review question.

[e]Not downgraded for imprecision because the 95% CI did not include the null value and consistently favored the intervention.

[f]Formal statistical assessment of publication bias was not performed because fewer than 10 studies contributed to each outcome; no downgrade was applied for publication bias.

[g]Downgraded one level for serious inconsistency because the point estimates differed materially across studies and considerable heterogeneity was present (I^2=89.4% - 93.3%).

[h]Downgraded one level for imprecision because the 95% CI included both no effect and a potentially important benefit.

[i]MD: mean difference.

[j]Downgraded one level for risk of bias because one of the 3 contributing studies was rated as having a high overall risk of bias.

Additionally, the digital interventions for HA can be categorized into guided and unguided DTs, each with distinct characteristics. Table 3 summarizes the analytical results of digital interventions for HA, categorized primarily by guidance type into guided and unguided digital therapies. In the guided digital therapy subgroup, the majority of studies (n=10) [44-52,59] used RCT or CS designs, with intervention durations to 12 weeks. These studies were predominantly conducted in Sweden (n=5) [44,45,47,52,59], Denmark (n=4) [49,53,57,58], and Australia (n=2) [46,48], using HAI or SHAI as primary outcomes, often in combination with the Whiteley-7 Index. A key finding was that, except for one small single-case study, all guided interventions reported significant reductions or improvements in primary outcomes, with most including follow-up periods ranging from 3 to 12 months, indicating the durability of digital intervention effects on HA.

In contrast, studies of unguided digital therapies exhibited greater heterogeneity, with intervention durations ranging from 12-week RCTs to single-session interventions (eg, 12 minutes or 7 days). These studies were conducted across a broader geographic distribution, including Sweden (n=1) [44], New Zealand (n=1) [56], the United States (n=1) [51], Australia (n=1) [55], China (n=1) [50], and Japan (n=1) [54]. Although most nonguided interventions have reported significant efficacy, some short-term pilot studies (eg, 14 days) or single-session interventions failed to show significant results. These approaches encompass formats such as unguided ICBT, self-help reading materials, video testimonials, and mobile-based iCBM-I. Additionally, 2 studies [51,56] (involving chatbots and computerized anxiety sensitivity interventions) found no significant effects. These descriptive patterns suggest that the guidance model and intervention dosage might be important factors.

XSL•FO
RenderX

The RCT included 3 intervention groups, including ICBT, unguided ICBT, and bibliotherapy. Since both guided and unguided intervention formats are involved for each group, they appear twice in the article.

Discussion

Principal Findings

This systematic review and meta-analysis examined the effectiveness of digital interventions for health anxiety across 16 studies, including 9 RCTs. Six RCTs involving 585 participants contributed to the primary meta-analysis and showed a significant reduction in health-anxiety symptoms (Hedges *g*=–0.77, 95% CI –1.25 to –0.30; *P*=.002). By contrast, pooled effects for IAS, BAI, ASI, and MADRS-S, although generally favoring digital interventions, did not reach statistical significance. Because no formal comparisons between outcomes were conducted and the analyses used different effect measures, this pattern should not be interpreted as proof that the effect on HA was statistically larger than the effects on broader psychological outcomes. Considerable heterogeneity was observed across all outcomes (I^2=86.7% - 93.3%), while GRADE certainty was low for HA and very low for the secondary outcomes. Importantly, leave-one-out analyses showed that the health-anxiety effect remained significant after exclusion of any individual trial, with estimates ranging from Hedges *g*=–0.90 to –0.60, despite persistently high heterogeneity. In comparison, IAS and ASI became significant after exclusion of Axelsson et al [47], whereas BAI and MADRS-S remained nonsignificant throughout. Taken together, these findings indicate a statistically stable effect on health-anxiety-specific symptoms across leave-one-out analyses, whereas evidence for broader psychological outcomes remains less stable and more uncertain.

This pattern is broadly consistent with the mechanisms targeted by the included interventions. HA is characterized by catastrophic interpretations of benign bodily sensations and is maintained by reassurance seeking, repeated checking, and avoidance [62,63]. CBT directly targets these processes through exposure and cognitive restructuring [64], whereas ACT seeks to reduce behavioral restriction associated with illness-related thoughts and promote engagement in meaningful activities [65]. Digital delivery may further support structured practice, symptom monitoring, and repeated therapeutic exercises [66], while its accessibility and privacy may reduce barriers to conventional psychological care [67,68]. The observation that the pooled effect was significant for HA but not for the broader psychological outcomes may also reflect measurement specificity. HAI and SHAI directly assess illness-related worry, bodily vigilance, and fear of illness and therefore closely correspond to illness-focused treatment targets, whereas BAI, ASI, and MADRS-S capture broader anxiety-related or depressive symptoms. Although these constructs overlap with HA, they are not necessarily primary treatment targets [69,70]. Accordingly, reductions in illness-related catastrophic interpretations may occur without parallel improvements in general anxiety or depressive symptoms [71]. Nevertheless, the present meta-analysis cannot determine which therapeutic components or measurement characteristics account for this differential pattern.

Beyond outcome specificity, variation in intervention intensity and clinical presentation may also have contributed to the heterogeneous findings. Intervention duration ranged from a single 12-minute session to programs allowing completion within 90 days, although structured 12-week programs were most common. From a descriptive standpoint, positive outcomes were more consistent in interventions that were longer in duration and guided; this may be linked to the greater willingness of anxious individuals to engage in “in-person social interactions” or “real-world activities” that serve to shift attention. In contrast, several brief or unguided interventions failed to yield significant results. However, duration was not formally evaluated as a moderator, and treatment length was intertwined with differences in intervention content, population, comparator, and outcome assessment. Therefore, this pattern should be regarded as hypothesis-generating rather than evidence of a dose-response relationship. Clinical heterogeneity adds further uncertainty. The included populations encompassed SSD, IAD, hypochondriasis, severe or subclinical HA, COVID-19-related HA, cyberchondria, HA associated with physical illness, and HA by proxy. Differences in baseline severity, comorbidity, and the nature of the perceived health threat may therefore have contributed to between-study variability and limit the extent to which a single pooled estimate can represent all presentations of HA.

At a broader conceptual level, this clinical diversity is relevant to the continuing debate concerning the nosological position of HA. Although *DSM-5* classifies IAD and SSD within “Somatic Symptom and Related Disorders,” HA shares several cognitive and behavioral features with generalized anxiety disorder, panic disorder, and obsessive-compulsive disorder, including threat hypervigilance, catastrophic interpretation, and excessive safety behaviors [72]. HA has therefore been proposed to fall, at least partly, within an anxiety-spectrum framework [73]. The present findings are compatible with, but do not establish, this interpretation. In particular, the favorable response of health-anxiety symptoms to interventions largely derived from established anxiety treatments, especially CBT, is consistent with previous evidence [74]. However, the absence of significant pooled effects on BAI and ASI indicates that treatment response alone cannot resolve its nosological classification. A related distinction may also exist between persistent HA and more context-dependent disease-specific fear. The included COVID-19-related study suggests that digital interventions may be applicable to both presentations [58], while longer-term evidence indicates that health-anxiety and general-anxiety trajectories may remain related over time [75]. Thus, future studies may benefit from examining whether more state-like versus trait-like characteristics influence treatment response and maintenance rather than assuming that HA represents a clinically uniform construct.

The distinction between guided and unguided interventions should likewise be interpreted cautiously. Narratively, favorable outcomes appeared relatively consistent across many guided ICBT- and internet-based acceptance and commitment therapy (iACT)–based interventions, whereas unguided interventions

XSL•FO
RenderX

showed greater variability. Therapist support may facilitate adherence, identify avoidance of therapeutic exercises, and strengthen engagement [66,76]. Nevertheless, the current evidence does not establish the superiority of guided interventions: some unguided or brief approaches also produced favorable outcomes, and direct comparisons have not consistently demonstrated significant between-group differences [44]. Moreover, guidance was confounded with intervention duration, therapeutic approach, and population characteristics. Its apparent advantage should therefore be viewed as a descriptive pattern requiring confirmation in adequately powered RCTs that directly compare otherwise equivalent guided and unguided programs. From a clinical perspective, digital interventions may consequently represent a potentially useful low-intensity or adjunctive option for HA, particularly where access to face-to-face psychological care is limited, such as in primary care, general hospital, geographically remote, or resource-constrained settings [12,77]. Their effects on health care use, long-term outcomes, and cost-effectiveness remain to be established.

Finally, implementation should consider digital health equity alongside effectiveness. Although remote delivery may reduce some barriers to psychological care, disparities in device access, internet connectivity, digital literacy, language, and socioeconomic resources may restrict participation among some populations. Accessible interfaces, culturally and linguistically adapted content, appropriate user support, and alternative routes to care should accompany future implementation. Overall, the present review provides evidence that digital interventions can reduce core health-anxiety symptoms, with the primary effect remaining robust across sensitivity analyses. The pooled effects on broader psychological outcomes were nonsignificant, while guided delivery, intervention intensity, and clinical phenotype remain plausible but unconfirmed explanations for between-study variation. Future RCTs should clarify which patients benefit most and under what delivery conditions.

Limitations and Potential of the Study

Several methodological limitations constrain confidence in these findings. First, the quantitative evidence base was limited. Although 9 RCTs were included, 6 contributed to the primary meta-analysis, and most secondary-outcome meta-analyses contained only 3 or 4 trials, restricting precision and the ability to evaluate the robustness of pooled findings. This protocol deviation should be considered when interpreting the robustness of the findings. Second, among the 9 RCTs, 4 had low overall RoB, 2 had some concerns, and 3 had high RoB. Measurement of the outcome was the most frequent source of high-risk judgments, particularly where participant-reported outcomes were used without blinding. Because participant blinding is inherently difficult in digital psychological interventions [78,79], expectancy effects, response bias, and outcome-measurement bias cannot be excluded. Future trials may strengthen assessment by combining self-report measures with blinded diagnostic evaluation and, where appropriate, behavioral, physiological, or sensor-derived indicators [44,80], while carefully designed active or sham digital comparators may help reduce differences in treatment expectancy [81].

Third, substantial statistical heterogeneity was observed, with I^2 values exceeding 80% for every pooled outcome and remaining high in most sensitivity analyses. No subgroup-difference tests or meta-regression analyses were undertaken; consequently, intervention type, guidance, duration, diagnostic status, and baseline severity cannot be regarded as established moderators. Clinical and methodological diversity may have contributed to this variability. The included populations represented several diagnostic and contextual presentations, and the interventions differed in therapeutic components, including exposure, cognitive restructuring, acceptance-based strategies, and bias modification. Differences in duration, professional guidance, adherence, comparators, and assessment timing may have further contributed to variation in the effect estimates.

Fourth, where follow-up was reported, most periods were 6 months or less, leaving the longer-term durability of digital interventions uncertain. In addition, pooled RCT estimates did not demonstrate statistically significant effects on IAS, BAI, ASI, or MADRS-S. This finding should not be generalized to every individual study and remains uncertain because of the small number of contributing trials, substantial heterogeneity, and limited precision. Publication bias could not be formally assessed because fewer than 10 studies contributed to each meta-analysis, and unpublished null findings cannot be excluded. Overall, the low GRADE certainty for the primary outcome and very low certainty for the secondary outcomes preclude strong clinical recommendations.

Despite these limitations, digital interventions remain promising accessible and scalable options for HA, particularly where face-to-face care is limited. To translate this potential into reliable clinical benefit, future research should prioritize several directions.

First, RCTs should directly compare the long-term effectiveness and cost-effectiveness of internet-delivered and face-to-face CBT. Second, predictors such as baseline severity, comorbidity, digital literacy, and treatment preference should be examined to improve matching between guided and unguided interventions. Third, rapid diagnostic tools should distinguish SSD, IAD, and nondiagnostic presentations in primary care and evaluate the added value of health-literacy education [82]. Fourth, studies should test whether somatosensory technologies improve engagement and adherence. AI should follow principles of transparency, data minimization, and clinical oversight [83]. Because severe HA may involve distress during exposure or unintended interpretations of digital content, evidence is needed on the suitability of self-guided interventions for patients with suicidal ideation, psychotic disorders, or severe physical illness. Future systems should include risk monitoring and clear escalation pathways [84] to support safe and trustworthy digital mental health care. Finally, alongside these clinical and methodological priorities, future implementation and research must consider digital health equity, including access, literacy, and cultural adaptation, to ensure that these interventions benefit diverse populations

XSL•FO
RenderX

Conclusions

The available evidence suggests that digital interventions can reduce core health-anxiety symptoms, with the pooled effect remaining significant across sensitivity analyses. However, substantial between-study heterogeneity, risk-of-bias concerns, and low certainty of evidence limit confidence in the magnitude and generalizability of this effect. Evidence for illness-related attitudes, general anxiety, anxiety sensitivity, and depressive symptoms remains inconclusive, and the current data do not establish which intervention formats, levels of guidance, or patient characteristics account for differences in treatment response. Digital interventions may therefore represent a potentially useful low-intensity or adjunctive option for HA, particularly where access to conventional psychological care is limited, but firm conclusions regarding broader psychological benefits and long-term effectiveness cannot yet be drawn. Adequately powered, well-reported RCTs using rigorous outcome assessment, appropriate active comparators, and longer follow-up are needed to confirm these findings and clarify which patients benefit most and under what delivery conditions.

Abstract

Background: Gender-affirming voice training (GAVT) has reduced gender incongruence for transgender and gender-nonconforming (TGNC) individuals, but remains limited by cost and scarcity of specialized providers. Mobile health (mHealth) is a bridge to these access gaps; yet, few high-quality, clinically informed mHealth apps exist within voice clinical sciences.

Objective: We previously created a free mobile app (Attuned; Weill Cornell Medicine and Ithaca College) to deliver clinically informed GAVT through structured instructional videos narrated by a speech-language pathologist and a laryngologist, practice exercises, and pitch-tracking tools, developed with a community advisory board of TGNC individuals. This mixed methods study aimed to assess the app's usability and users' impressions.

Methods: Adult TGNC individuals were recruited nationwide via word of mouth and advertising through lesbian, gay, bisexual, transgender, queer, or questioning (LGBTQ+) community organizations. Participants completed a baseline semistructured interview and demographics survey, used Attuned for one week, and completed a second interview regarding their impressions. Interviews were transcribed verbatim and coded inductively in MaxQDA (VERBI Software GmbH). Three authors independently generated codebooks that were reconciled via consensus, then 2 authors applied the finalized codebooks to the remaining transcripts (preconsensus agreement 95.7%; Cohen κ=0.86). Attuned was also evaluated by 2 reviewers experienced in mHealth evaluation and not involved in the app development, using the Mobile App Rating Scale (MARS), the Intercontinental Medical Statistics (IMS) Institute for Health Care Informatics Functionality Scores, the Centers for Disease Control (CDC) Modified Clear Communication Index, the Institute of Medicine (IOM) strategies for creating health-literate mHealth apps, the Patient Education Materials Assessment Tool (PEMAT), and the System Usability Scale (SUS). Readability of the didactic scripts was also assessed with 6 validated formulas.

Results: Eighteen TGNC individuals completed the study (median age 27.5 years, age range 19 - 50 years). Ten identified as women and/or transgender women, 6 as nonbinary or gender-nonconforming, and 2 as men or transgender men. Eight themes were identified. Participants identified voice as a crucial determinant of others' perceptions of their gender, with voice-related dysphoria common. Cost and difficulty finding providers were primary barriers to GAVT, and existing free resources were viewed as unstructured and untrustworthy. Postuse impressions were largely positive, particularly regarding the structured curriculum, pitch tracker, convenience, and free access, though lack of individualized feedback was a key limitation. Mean scores were 4.21/5 (SD 0.53) for MARS; IMS functionality, 6.5/11 (SD 0.7); CDC index, 82.5% (SD 24.7%); IOM strategies, 28.5/33 (SD 2.1); and

XSL•FO
RenderX

PEMAT understandability and actionability 100%, and SUS 92.5/100 (SD 10.6), with most readability formulas at or below an eighth-grade level.

Conclusions: Voice is central to gender identity for TGNC individuals; yet, structured and affordable GAVT remains largely inaccessible. Attuned was positively received by this initial cohort and scored highly on usability, health literacy, and readability, though findings are limited by potential acquiescence bias and the raters' authorship roles.

transgender persons; gender-affirming; voice training; mobile apps; qualitative research; mixed methods

Introduction

Transgender and gender-nonconforming (TGNC) individuals are people whose gender identity is distinct from the sex they were assigned at birth [1]. Prior studies have reported that as many as 96% of TGNC individuals report experiencing voice-gender incongruence, defined as a lack of alignment between an individual's gender and the perceived gender of their voice [2]. Voice has been shown to be intricately linked to TGNC individuals' self-perception of gender identity, with subsequent profound effects on quality of life [3,4]. Voice modification is thus a part of many individuals' transition; the standard of care for these patients, potentially alongside hormonal and/or surgical treatments, is gender-affirming voice training (GAVT). GAVT has a growing evidence base supporting its efficacy, both for objective voice parameters and for patient-rated satisfaction [5-10]. While many individuals focus on pitch modification for gender affirmation, many other factors, including resonance, word choice, syntax, and intonation, influence perception of vocal femininity or masculinity, solidifying the crucial importance of GAVT for optimal gender-affirming voice modification [11-13]. However, there is a relative scarcity of qualitative research on GAVT. This is a significant shortcoming given the known difficulties of quantitative measurements in this area, including poor correlation between various patient-reported outcome measures and objective acoustic measurements [5,14].

Although 70% of TGNC individuals desire gender-affirming voice care, they face barriers to health care at much higher rates than the general population [15-18]. There is thus a significant unmet need for GAVT among TGNC patients, fueled by many factors such as relative scarcity of qualified and affirming providers, difficulty obtaining insurance coverage or acquiring necessary funds to pay out-of-pocket, and the fears of many TGNC individuals in engaging with the health care system [16,19,20]. This gap also has implications for research into the demand and desires for GAVT, since both quantitative and qualitative studies are primarily limited to TGNC individuals who are already presenting for GAVT, thus missing the broad swath of individuals who are not able to access it.

Mobile health (mHealth) represents a promising avenue to reduce such gaps in access for this important care, but uptake of mHealth in voice-focused health care by laryngologists and speech-language pathologists (SLPs) remains limited [21]. A recent publication by our group identified fewer than 30 clinically relevant apps within laryngology, many of which scored poorly on evaluations of usability, health literacy, and readability [21]. The relative paucity of mHealth in our field is particularly striking given that conditions under the purview of laryngology—such as chronic cough, gastroesophageal reflux disease, dysphagia, and dysphonia—are extremely common. As the capabilities of digital health and mHealth tools grow, there remains a critical unmet need for high-quality, evidence-based, and accessible mHealth apps within laryngology.

Our group has previously described the creation of a free mobile app providing clinically informed GAVT, "Attuned" (Weill Cornell Medicine and Ithaca College) alongside a community advisory board (CAB) of TGNC individuals, with the goal of closing the gap in delivery of crucial gender-affirming health care [22]. Attuned consists of multiple modules of instructional videos covering voice physiology and laryngeal anatomy, pitch, intonation, resonance, volume, articulation, and syntax. Rather than offering separate feminization and masculinization tracks, each module presents the relevant vocal parameter as a spectrum and teaches techniques for shifting the voice in either a more feminine or more masculine direction, allowing users, including nonbinary users whose goals may not align with a binary framework, to apply the same curriculum toward their individual voice goals. The curriculum is narrated by an SLP and a laryngologist who deliver gender-affirming care in their clinical practice; this content is based on the standard of care in GAVT and was iterated with feedback from the CAB to provide maximum understandability and utility to the target user base. The app also includes other features, such as assigning "homework" assignments and practice exercises, the ability to record voice samples and track vocal pitch over time, and a piano keyboard to provide reference pitches for pitch modification.

In this study, we undertook a mixed method approach to evaluate Attuned for the first time: (1) a qualitative study investigating TGNC individuals' preexisting perceptions of their voice and voice modification as well as their reactions and feedback following the use of Attuned, and (2) a battery of validated scales to assess the app's usability, functionality, and readability.

Methods

Overview

We used a convergent mixed methods design [23], in which qualitative data (semistructured interviews) and quantitative data (validated mHealth assessment scales and readability measures) were collected in parallel and analyzed independently and integrated at the interpretation level through narrative

XSL•FO
RenderX

weaving by comparing qualitative themes with quantitative scale domains.

Qualitative Study

To maximize diverse subjective feedback, a qualitative study design was used to capture TGNC individuals' baseline attitudes about voice and gender and their reactions to the Attuned app. The qualitative component of this study is reported in accordance with the COREQ (Consolidated Criteria for Reporting Qualitative Research) [24]; the completed checklist is provided in Checklist 1. Adult (≥18 years) individuals identifying as transgender, nonbinary, or gender-nonconforming were recruited via word of mouth and advertising through lesbian, gay, bisexual, transgender, queer, or questioning (LGBTQ+) community organizations nationwide. Participants were required to have access to an iPhone, since the first version of Attuned was available only for iOS at the time of our study. Recruitment was particularly focused on representing a wide array of gender identities, and sample size was determined by thematic saturation [25,26]; in total, 18 individuals participated.

Following informed consent, participants engaged in a one-on-one semistructured interview with one of 2 members of the research team (ILA or CPK) and completed a demographic survey. They were then given access to the Attuned app for one week and instructed to experience as much didactic material as possible. Following one week, participants were re-engaged for an additional semistructured interview, focused on their perspectives of the Attuned app and its delivery of GAVT. Screenshots of the app are shown in Figure 1. Interview questions were devised by the study team to collect information regarding (1) baseline attitudes about the voice and its relationship with gender, (2) prior experience with and impressions of voice training or self-driven voice modification, (3) impressions of the Attuned app in particular, and (4) reflections on the value and shortcomings of GAVT delivered by mHealth. Interviews were conducted via Zoom (Zoom Communications, Inc), and recordings were transcribed verbatim using a combination of Zoom's built-in transcription (using a Health Insurance Portability and Accountability Act [HIPAA]–compliant Zoom platform) and the Whisper transcription app by OpenAI (which was run locally and through terminal, thus also achieving HIPAA compliance) [27]. Transcriptions were reviewed for accuracy by the individual who conducted the interview. All interviews took place between February and April 2025.

Interview transcriptions were coded using MaxQDA software (VERBI GmbH). Coding followed an inductive thematic analysis as described by Braun and Clarke [28]. Three authors (ILA, CPK, and RC) independently reviewed and coded the transcripts of the first 3 participants, both pre- and post-use interviews (ie, 6 transcripts in total). The 3 codebooks were then compared and reconciled through consensus discussion among all 3 coders to generate a finalized codebook. Prior to consensus discussion, inter-rater reliability of coding was calculated within MaxQDA, and the percent agreement was 95.7%, with a Cohen κ of 0.86, corresponding to near-perfect agreement. Two authors (ILA and CPK) then independently applied the finalized codebook to all remaining transcripts, with coding differences again reconciled via consensus discussion. No code required adjudication by a third coder. New codes arising during coding of the remaining transcripts were added to the codebook by consensus, and previously coded transcripts were reviewed again with the updated codebook. Thematic saturation was assessed following the approach of Guest et al [25], defined a priori as the point at which successive interviews yielded no new codes or themes. Codes were grouped into candidate themes and consolidated into 28 subthemes, which were reviewed and refined by the coding team into the 8 final themes reported below.

XSL•FO

Figure 1. Logo and screenshots of Attuned app interface.

Objective Assessment of Attuned

Two authors (IC and EO), with previous experience evaluating mHealth apps via validated scales and who were not involved in the development of Attuned, completed ratings via Google Forms. In line with prior systematic assessments of mHealth apps by members of our authorship team [21], the following scales were used: (1) the Mobile App Rating Scale (MARS) [29], (2) the Intercontinental Medical Statistics (IMS) Institute for Health Care Informatics Functionality Scores [30], (3) the Centers for Disease Control (CDC) Modified Clear Communication Index [31], (4) the Institute of Medicine (IOM) strategies for creating health-literate mHealth apps [32], (5) the Patient Education Materials Assessment Tool (PEMAT) [33], and (6) the System Usability Scale (SUS) [34]. No single validated scale captures quality, functionality, health literacy, and usability, so we applied the same multiscale battery used in our group's prior systematic assessment of laryngology apps [21] to permit direct comparison with other apps. Scores were averaged between the 2 raters. For each of these scales with explicitly numerical output evaluated by 2 raters, interrater reliability was evaluated via calculation of an intraclass correlation coefficient (CA-ICC). Readability of the script used for didactic videos was also assessed using 5 validated readability formulas via Readable.io (Added Bytes Ltd) [35]: (1) Flesch-Kincaid Reading Level and Flesch-Kincaid Reading Ease [36], (2) the Gunning Fog Index [37], (3) Coleman-Liau Index [38], (4) Simple Measure of Gobbledygook (SMOG) Index [39], and (5) New Dale-Chall [40]. As previously described, it is standard to use multiple readability scales, as there is no established gold standard [41]. Each readability formula is calculated differently, focusing on various attributes of a given text selection such as word and sentence length, number of unfamiliar words, number of syllables, and sentence structure complexity. Briefly, the Flesch-Kincaid Reading Ease score ranges from 0 to 100 and is inversely related to readability, while the remaining scales describe a grade level of education necessary to understand the text [41].

Positionality Statement

The research team would like to formally acknowledge that our individual and collective identities may influence our research. We have opted to share information about the identities of the primary members of the research team who designed and conducted the majority of the present study.

ILA and CPK are both medical students and cisgender members of the LGBTQ+ community and are both advocates for gender-affirming care and the TGNC community. AR is a fellowship-trained laryngologist at the Sean Parker Institute for the Voice at the Weill Cornell Medical College, who completed her training at Stanford University and then at the University of California, Davis. She is a cisgender member of the LGBTQ+

XSL•FO
RenderX

community and an ally of the TGNC community. KAC is a fellowship-trained laryngologist at Stony Brook Medicine specializing in LGBTQ+ care, who trained at Oregon Health & Science University and then at the Sean Parker Institute for the Voice. He is a cisgender member of the LGBTQ+ community and an ally of TGNC people. MP is an SLP who trained at Ithaca College and later returned to direct the speech-language pathology clinic at the same institution. She is a cisgender woman and an LGBTQ+ ally. RC is a voice-specialized SLP, focusing on care of the professional voice and gender-affirming voice care (among other clinical specializations) at the Sean Parker Institute for the Voice, which trained at the Massachusetts General Hospital's Institute of Health Professions. She is a cisgender woman and an ally to the LGBTQ+ community. All 6 team members underwent cultural humility training prior to beginning the development process.

Ethical Considerations

This study received approval from the Weill Cornell Medical College Institutional Review Board (#22 - 09025226). Informed consent was waived for this study, as the research presented no more than minimal risk to the participants and involved no procedures for which written consent is normally required outside of the context of research. Participants were provided with a study information sheet prior to joining the study. Participants were assigned a participant ID in REDCap (Vanderbilt University), and all survey data were captured in REDCap. Interviews were conducted over Zoom, and once the interviews were transcribed and all personal identifiers were redacted from the transcript using Whisper by OpenAI, which was run offline, the audio recordings of the interviews were destroyed upon completion of the study. Audio recordings and deidentified transcripts were stored locally on a password-protected tagged device and labeled with the participant ID. Participants received US $30 for their participation in the study and were compensated by ClinCard (Greenphire LLC).

Results

Qualitative Study

Participant Characteristics

A total of 18 interviews were conducted from February to April 2025. Of the 18 participants, 10 identified as women and/or transgender women, 6 identified as nonbinary, gender-nonconforming, or gender fluid, and 2 identified as men or transgender men. Ten used the pronouns she/her, 2 used the pronouns he/him, 4 used the pronouns they/them, one used the pronouns she/they, and one used the pronouns he/she/they. Ten individuals were assigned female at birth (AFAB), 7 were assigned male at birth (AMAB), and one was intersex.

Twelve participants had a history of hormone replacement therapy. Of the 12 participants, 3 had received testosterone treatment and 9 had received one or more of the following treatments: estrogen, progesterone, and spironolactone. Twelve participants also self-reported as being under the neurodivergent umbrella.

The median participant age was 27.5 years, with ages at the time of interview ranging from 19 to 50 years. A summary of these and additional participant characteristics, including geographic regions and settings (urban, suburban, or rural) as defined by the US Census Bureau, is shown in Multimedia Appendix 1.

Overall Qualitative Results and Themes

Prior to consensus discussion, interrater reliability was calculated within MaxQDA (VERBI Software GmbH) software; percent agreement was found to be high at 95.7%, with a Cohen κ of 0.86, corresponding to near-perfect agreement. Eight overarching themes were identified (5 from pre-Attuned interviews and 3 from post-Attuned interviews) and will be described individually below: (1) the voice is essential to gender identity, (2) dissatisfaction with the voice is the norm, (3) high-quality voice training is largely inaccessible, (4) navigating and modifying the voice across social contexts, (5) current apps fall short of user needs, (6) Attuned provides a clear curriculum with useful features on users' own schedules, (7) Attuned can positively impact the voice, and (8) Attuned is limited by lack of immediate feedback and personalization.

The Voice Is Essential to Gender Identity

Exemplar quotes pertaining to the importance of voice to gender identity are shown in Table 1. Many participants emphasized that their voice was a key part of their own self-conception of their gender and gender presentation as well as their self-confidence (Q1-Q3), while also stressing its "paramount" effects on others' perceptions of their gender (Q4-Q7). The voice was identified as a "tell" or a "giveaway" when they felt they could otherwise "pass" or be identified as a cisgender person of the gender to which they had transitioned [42]. Many participants felt that their voice was a reason for being misgendered or assigned a gender different from the one with which they identified (Q8-Q11) [43]. Importantly, several participants noted that being either misgendered or identified as a transgender person may have implications for their safety.

XSL•FO
RenderX

Table . Exemplar quotations: the voice is essential to gender identity.

Subtheme	Exemplar quotations
Voice's impact on self-conception of gender	• Q1: "It's how I express myself. All the little sounds I make, everything that I say, it's just a part of who I am. It's important." (P1) • Q2: "I think having the right pitch can really help me in my transition and formation of my gender identity. It is really important in the transition process and becoming blended into society as the person and gender I identify with." (P2) • Q3: "What's most important to me is how I see myself, and just having confidence in my voice, which would make me speak up more and use my voice." (P16)
Voice's impact on others' perceptions of gender	• Q4: "I think my voice is very important because the first time I open my mouth when I'm talking to someone, they can easily assume my gender based on my voice and how I talk." (P2) • Q5: "If you know the old saying: 'If it walks like a duck, looks like a duck, and quacks like a duck, then it's a duck.' Well, I look like a duck, but I don't quack like a duck. So, yeah, it's one of those things where I've seen people turn around expecting me to be a guy because they hear my voice, and they turn around and are confused because I'm not a guy." (P16) • Q6: "I'd say it is paramount to passing in my everyday life." (P21) • Q7: "The fact that it's possible that I could be passing without it and then completely tarnish it the second I speak is something that weighs on me every single day." (P28)
Misgendering and safety	• Q8: "If people can't see me physically like on the phone or at the drive through, they say ma'am. They assume based on the way they hear my voice that I'm a woman." (P5) • Q9: "You know, there are situations where either for professionalism or for safety or just comfort, it is helpful or convenient to have voice modification available." (P11) • Q10: "But when I had shorter hair and more loosely fitting clothing, my gender became a question and you could tell because people start giving you the look and are wondering to themselves 'What's going on? What do I say?' But then, I would open my mouth and they would immediately gender me as a woman." (P12) • Q11: "Yes, I have been misgendered on the telephone. Certainly, in face-to-face situations, where I feel like I am either presenting in a nonbinary, feminine-leaning way. Or, I feel like I'm totally presenting as female, maybe not passing. So it's hard to tell if it's transphobic responses or ignorant, internal bias responses, or just responding to my voice, but I feel like my voice 'clocks' me a lot and gets me misgendered." (P35)

Dissatisfaction With the Voice Is the Norm

Exemplar quotes regarding participants' current dissatisfaction with their voice are given in Table 2. Many individuals cited particular aspects of their voice that they were dissatisfied with, including pitch being too high or too low, or a lack of control over specific sounds, while others felt that their voice was generally "not the way I would like my voice to be" (Q12-Q15). In addition, voice was identified as a source of dysphoria, defined as stress derived from incongruence between one's gender identity and the gender they were assigned at birth [44]. Some participants noted their voice was a "main cause" for their dysphoria (Q16-Q18). Dysphoria related to the voice was often severe enough to make participants "cry about it" or require them to "pause and...reset at times in conversation." Accordingly, there was a substantial desire to modify the voice, ranging from technical changes such as pitch modification to more abstract feelings of wanting to "pass" or to align their voice with "how I feel inside" (Q19-Q23). Several participants also shared their experiences with voice modification via gender-affirming hormones, particularly testosterone for voice masculinization. Some individuals feared the potentially irreversible effects of hormones, while others who had used testosterone noted that despite improvements in vocal pitch, the hormone did not allow them to achieve a voice truly in line with cisgender men, but rather often outed them as transgender (Q24-Q30).

XSL•FO
RenderX

Table . Exemplar quotations: dissatisfaction with the voice is the norm.

Subtheme	Exemplar quotations
Dissatisfaction with voice	• Q12: "I am not satisfied with much because it's not really the way I would like my voice to be." (P2) • Q13: "When I try to just let myself be heard, it tends to just go much deeper than I intended to and I don't realize until I'm mid-sentence." (P13) • Q14: "I'd say that the satisfaction with my voice has gone down over time, as the rest of me has evolved to fit my ideal image that then it just makes the voice even more important, because it's kind of like the last piece." (P16) • Q15: "I'm dissatisfied with the fact that it gives me away and the fact that it is masculine." (P28)
Voice causes dysphoria	• Q16: "It's the main cause of my dysphoria." (P21) • Q17: "It depends on the day. It depends on how I'm feeling. I'd say my voice definitely causes moderate dysphoria. But there are some times where it's mild and I forget about it. There are sometimes where it's severe and I cry about it." (P28) • Q18: "Recently I've been experiencing quite a bit of dysphoria at times surrounding my voice, to the point where I sort of pause, and have to close my eyes and reset at times in conversation." (P35)
Desire for voice modification	• Q19: "Just being able to talk to somebody in the bathroom would be really great without having anyone feel uncomfortable." (P1) • Q20: "I want my voice to be deeper." (P6) • Q21: "I would like to present in the world based on how I feel inside." (P10) • Q22: "I guess my goal would be probably to 100% pass as a female." (P16) • Q23: "I would just like to be able to speak in a softer, more breezy, feminine way, and do so naturally. It's a lot of effort at the moment to even try to think about it, and I feel silly at times, even practicing." (P35)
Impact or perceptions of gender-affirming hormones	• Q24: "It feels almost like a catch 22, like, yes, I want my voice to be deeper and all of these things. I want to do this masculinizing therapy. But people's perception of my voice being different and my vocal cords changing with the testosterone too, causing my voice to be nasally, would then actually make me feel probably more dysphoric than whatever voice my voice had been before." (P6) • Q25: "My voice was changing, and people could tell that it was changing. So their perception of my voice was like, oh, that person is trans or queer. So that was suddenly a reason that I had to start coming out, because my voice was obviously changing and things about my body were changing." (P6) • Q26: "HRT is really interesting and but not something that feels right for me at this time and it feels too permanent." (P17) • Q27: "I definitely still have the voice crack, the pubescent boy voice crack, which is not what I want to sound like." (P19) • Q28: "One of the things I've noticed in the past year on HRT is not only does my voice sound different, but I get like vocal cord exhaustion in a way that I never did before. So I talk a lot and I get more tired from it, which is a new experience." (P19) • Q29: "There's a particular sound to a trans guy kind of voice, and I feel like people hear that particular kind of quality and they notice that it's different enough and funny-sounding enough that it triggers a pause and curiosity response. And I think that is a significant part." (P19) • Q30: "But overall, in terms of just pitch in general, just talking, it does feel better." (P19)

High-Quality Voice Training Is Largely Inaccessible

Exemplar quotes pertaining to experiences and perceptions of formal or informal voice training are given in Table 3. A few participants recounted mixed impressions of formal voice training with a one-on-one coach or SLP; while such endeavors were often productive, they often failed to meet initial expectations, potentially yielding frustration after spending "so

XSL•FO
RenderX

much money on therapy" and still being "misgendered over and over and over again" (Q45-Q46). Some participants also highlighted the utility of nongender-focused voice training for better voice control, which could be leveraged in service of gender-oriented voice modification (Q47). However, the majority of participants had not had prior experience with formal voice training of any kind, citing several key barriers to accessing it, including cost ("prohibitively expensive"), lack of specialized providers, lack of convenience or difficulty with time commitment, and difficulty navigating the landscape of resources to find a voice coach (Q48-Q52). Participants also shared various impressions of free, publicly available resources such as YouTube (Google LLC) videos or posts on social media forums, including Reddit (Reddit, Inc) and TikTok (ByteDance). While such resources provided some benefit, particularly when created by fellow members of the transgender community, navigating the unstructured information from countless sources was often frustrating, and the information shared was sometimes either not what participants were looking for or perceived as unreliable (Q53-Q57). Thus, many individuals still felt a strong desire for formal voice training in order to have a professional guide them through the steps and different aspects of voice modification (Q58-Q61).

XSL•FO
RenderX

Table . Exemplar quotations: high-quality voice training is largely inaccessible.

Subtheme	Exemplar quotations
Prior experience with voice training	• Q45: "I had a couple sessions for vocal training but that was really hard to sit in front of somebody on Zoom and try to change your voice." (P1) • Q46: "I had a moment a few months ago of feeling like I spent so much money on therapy and I spent so much time and effort on this and I was just getting misgendered over and over and over again. I had a period of time where it just kept happening and it was getting really frustrating. Sometimes it bothers me. Sometimes it doesn't. And I've had panic attacks over it. But it's not a consistent thing." (P11) • Q47: "I am lucky in that I have vocal training as an actor and so I feel like I have more control of my voice than I may have otherwise." (P17)
Difficulty accessing formal voice training	• Q48: "I am working 2 jobs so I cannot make a weekly hour session with either a speech therapist or vocal trainer." (P12) • Q49: "I have considered doing vocal training. But then, you know, it's obviously not covered by insurance and that's something that I'm paying for out of pocket. And because of that, it does not become a priority." (P12) • Q50: "Then, you have to find one for a really specific thing. You might even get someone who is not the right fit. Being nonbinary, it's a little more fuzzy because I am not looking for someone to tell me, 'Here's how you speak like a man' because I am not into that." (P12) • Q51: "I'm aware that there are like people who do voice coaching specifically for people in my situation. I've looked into it, but it's prohibitively expensive." (P19) • Q52: "I'm not even sure where to find one. Like vocal coach dot com? I think I just don't know where or who or how to acquire one." (P31)
Experience with publicly available resources	• Q53: "I never had consistency with those people. Like I see a TikTok video and they say some things and I can try them on my own, but I don't have anything consistent." (P6) • Q54: "I would like to have resources to have a lower pitch feminine voice, but all the resources I have access to are attempting to teach you to do use a hyper-femme voice before saying that you can maybe drop it down later. But there's no explicit path on how to do that." (P21) • Q55: "The voice resources I've tried so far, I would give them probably like a 5 or 6 out of 10. They really haven't yielded much success, but they haven't hurt either." (P21) • Q56: "I have accessed resources in an attempt to start doing something many times. I just it's very hard for me without like any sort of structure or guidance from interacting with another human or anything like that. I need something to set the routine for me." (P28) • Q57: "I have used a lot of YouTube videos. And I have found web page apps that that will help track certain aspects of my voice, and let me know what I have to work on. Although it's always hard to know what to trust on those apps, because some of them are not very accurate." (P36)

XSL•FO
RenderX

Subtheme	Exemplar quotations
Desire for voice training	• Q58: "I think if I get good training and I can change my voice, it can help, as long as it is also coupled with my physical appearance and clothing and such things. It can help people identify my gender much faster than before." (P2) • Q59: "It would probably be really effective to have like a one-on-one voice coach who was like talking me through doing things." (P3) • Q60: "I think a voice coach would probably be one of those things that would make a humongous difference. There's the technical aspects of your voice, but there's also ways of explaining things or saying things that are considered more masculine or feminine-like. So, someone that could have an outside perspective on how I'm being read or perceived would be something I would want." (P16) • Q61: "With any sort of training, control is really nice, and when you have control and knowledge, I think it gives you a lot of autonomy." (P17)

Navigating and Modifying the Voice Across Social Contexts

Exemplar quotes regarding self-guided attempts at voice modification are shown in Multimedia Appendix 2. Many participants, largely without any formal instruction, focused primarily on attempts to alter their pitch to better align with their gender (Q31-Q33). Some also identified other aspects of voice that they sought to modify for gender-affirming purposes, such as cadence, resonance, weight, and volume (Q34-Q36). For most participants, such modifications were situational, changing their voice in professional situations or based on the individuals to whom they were speaking, such as using a "girl voice…with my friends…then at work…I use my guy voice" (Q37-Q42). Some also highlighted a fear of vocal injury or a feeling that altering their voice felt "forced" or "uncomfortable" (Q43-Q44), especially in the absence of reliable instruction for voice modification.

Current Apps Fall Short of User Needs

Exemplar quotes for participants' prior experience with voice-focused apps and their priorities for an ideal voice-focused app are shown in Multimedia Appendix 3. Several participants reported using apps largely focused on pitch identification and classification of the voice as male, androgynous, or female, though many had doubts about the accuracy and reliability of such apps (Q62-Q65). Participants were also asked to identify key priorities for their ideal voice-focused app. Common priorities included personalization for an individual's particular goals, a clean user interface, the ability to play back recordings or receive automated feedback, clear information and instructions, and structured teaching with the ability to practice (Q66-Q71).

Attuned Provides Clear Curriculum With Useful Features on Users' Own Schedules

The final 3 sections describe themes from the interviews conducted following the week during which participants used the Attuned app. Exemplar quotes regarding participants' overall satisfaction with Attuned and their perceptions of its particular strengths and benefits can be found in Table 4. All participants expressed overall positive impressions of the app, and several stated they "would definitely recommend" it to others (Q72-Q76). Two areas of particular strength were the clear structure and order with which participants were guided through the curriculum (Q77-Q80)—a significant improvement over attempts to cobble together other "scattered and unorganized" free resources—and the pitch-tracking function, which is coupled with a piano keyboard for pitch identification and pitch targeting (Q81-Q83). Participants also highlighted the convenience of app-based delivery of GAVT, allowing people to learn at their own pace and use the app in a variety of settings (Q84-Q87). Access to this free app also eliminated price as a major "sticking point" for many individuals. Finally, participants appreciated the clear delivery of instruction and emphasized the feeling of trustworthiness that comes from receiving information from a trained speech-language pathologist and a team of creators who "know what they're doing" (Q88-Q91).

Table . Exemplar quotations: Attuned provides clear curriculum with useful features, on users' own schedules.

Subtheme	Exemplar quotations
Overall satisfaction with Attuned	• Q72: "It's much better than any other voice app that I've used." (P5) • Q73: "I'm not aware of any robust voice training services available like this. And I think it's very beneficial. I would definitely recommend for anybody who was trying to have some at home practice, either in between speech therapy sessions or by itself." (P11) • Q74: "I do think getting information about your body is very empowering, and I think that is something it does very well. I think it's information a lot of people don't have and would benefit from." (P19) • Q75: "I think it's a really wonderful starting point terms of educating you on terms and the different qualities of the voice that make it up. It's amazing." (P28) • Q76: "I think that if you don't have access to an in-person voice therapist, I think the app is a lot better than having to pore through forums and YouTube videos and stuff like that." (P32)
Appreciation of clear structure	• Q77: "I thought the general structure of progressively getting more difficult and having a pretty clear line of progression was useful for me." (P3) • Q78: "It's difficult, if you're just trying to do voice training in a DIY context or on your own, because everything is so scattered and unorganized in terms of community resources. So that aspect of it was very helpful of just saying, OK, do this and this and this and this and then do these things together." (P11) • Q79: "And throughout it, I really enjoyed how it built on each aspect. Especially if somebody's coming in without much knowledge of what goes into what makes a voice work and language and all of that, it can be really informative." (P17) • Q80: "I really liked the structure. It's so important in terms of like educating you on the terms and finding the motivation. It's the only reason I had never started before just because of the overwhelming nature with zero guidance. This puts you on a certain path and it's nice." (P28)
Pitch tracking function was particularly helpful	• Q81: "I thought that the little keyboard tool to show what frequency your voice is currently at and where you want to go was really great and helpful for getting a better sense of where I want to be." (P10) • Q82: "I don't tend to think of voice in terms of like 'Oh, these are actual like pitches, and these notes, have names.' So that was very interesting to actually be able to match and see that visually." (P12) • Q83: "I liked the piano. That was really helpful. And I liked the option to record right there. Some of the exercises I wouldn't have been able to do if I couldn't both be playing the note and also trying to make a noise." (P19)
Convenience and accessibility were key benefits	• Q84: "Today I was doing it during my dog walk, or last night I was working on it while I was lying in bed. The other day I did a couple of minutes, when I had nothing to do at work. So I like that you can do little spurts." (P6) • Q85: "I could be listening to things right before I go into a meeting or spaces where I know that people are going to be meeting me for the first time. And I want to have that moment of listening to the articulation lesson or returning to a practice, whenever it is most needed." (P17) • Q86: "I think access is the biggest benefit, because that is such a sticking point for so many people. Like, even if their insurance covers it, the logistics of that are a bear." (P32) • Q87: "For many of us who identify as transgender, it is nice that it is private. I felt safe and secure doing the training in the comfort of my home." (P36)

XSL•FO
RenderX

Subtheme	Exemplar quotations
Information was clearly delivered and felt reliable	• Q88: "It was obviously designed in close partnership with people who very much know what they're doing. So that definitely comes through in a way that makes it both fundamentally useful, but also credible." (P12) • Q89: "I think it does a really good job of entry-level, accessible education around what one can control around their voice." (P17) • Q90: "It is very legitimizing to have it come from an actual speech therapist." (P32) • Q91: "The material felt digestible and easy to understand. I also found that the length of each lesson was appropriate." (P36)

Attuned Can Positively Impact the Voice

Exemplar quotations focused on Attuned's effects on the voice are given in Multimedia Appendix 4. Some participants felt that the app had already begun to affect changes in their voices, both in terms of their own satisfaction with their voice and the way their voice was perceived by others (Q92-Q94). However, the majority of participants had not yet noticed changes in their voice after only a week but remained optimistic that the tools and skills they had learned from the app would impact their voice with time and dedicated practice (Q95-Q98).

Attuned Is Limited by Lack of Immediate Feedback and Personalization

Exemplar quotations pertaining to challenges and drawbacks of using Attuned, or app-based delivery of GAVT in general, are shown in Table 5. A primary concern shared by many participants was the lack of feedback from the app, with several expressing uncertainty whether they were performing the exercises correctly; the loss of face-to-face communication, including potential physical touch from a coach, was also highlighted (Q99-Q101). Relatedly, some participants also felt that the app had a limited ability to personalize the curriculum based on their particular goals and felt that a "personal relationship" with a voice coach was also a meaningful aspect of voice training that was lost via an app (Q102-Q104). Since the app was in its initial beta-testing phase during this study, many individuals also cited specific technical glitches, which sometimes made the app difficult to navigate or operate (Q105-Q107). Finally, some participants requested that more voices, particularly trans voices or voices representing different dialects of English, be included in the instructional content, since only cisgender voices lead to participants "not hearing [themselves]" represented (Q108-Q110).

XSL•FO
RenderX

Table . Exemplar quotations: Attuned is limited by lack of immediate feedback and personalization.

Sub-Theme	Exemplar quotations
Difficult to not receive feedback from another person	• Q99: "People are really key for how one speaks. You can be really loud and resonant on your own, but if you feel nervous in front of other people, that's something that can only come with practice. Working with a coach, or even small groups of other people doing it would help break down that closing in on your throat when you feel nervous. So I think most apps run into the need for human connection at some point." (P17) • Q100: "There's no feedback of like, 'Yes, that is actually the note you're making.' I have no idea. So there's a guessing element to it. That's an element of 'I don't really know if this is right.'" (P19) • Q101: "I think the lack of feedback from someone who's actually hearing you is something that makes a difference. So, if you have the means, I would still recommend going to actual voice training over just using an app." (P32)
Lack of personalization and personal relationship	• Q102: "It's not necessarily tailored to what you would want, instead of like getting that one on one work with like a speech pathologist or someone." (P10) • Q103: "I think that obviously you have a less personal relationship. It's an app versus actually building a client provider relationship. So there is a bit of that disconnect." (P12) • Q104: "I'd say that it's a very useful tool, specifically for people who are beginning their voice training journey, because what it lacks in personalization and makes up for with general ease of use." (P21)
Beta-testing version of app had glitches	• Q105: "The app was glitchy for me. Stuff didn't load consistently." (P3) • Q106: "There were a couple of technical things about the app that I figure were because it's in its beta stage. Sometimes I would have to close the app and reopen it to get things to work." (P6) • Q107: "I will say that they did have some technical difficulties with using the app." (P10)
Diversity of voices in video content would be appreciated	• Q108: "Obviously, I think there is some level of comfort that could be achieved, even an aspirational goal that you could assign by receiving training from somebody who is themselves a trans person who has pursued and completed voice training." (P11) • Q109: "I feel like there could have been more of a diversity of the trainers, which I figure you guys also know with the app very much in testing stages. I know that there were a few things read by the more masculine person, or maybe just one. But having a more diverse set of voices would be great. And it was all in standard American. So having like AAVE[a] or other dialects would be cool and great to see." (P17) • Q110: "I would have really appreciated if there were some trans voices. Cis women's voices, I know what those are supposed to sound like. And there was an element of not hearing myself that I think we're all very used to." (P19)

[a]AAVE: African-American Vernacular English.

Objective Assessment

MARS, SUS, and IMS scales were used to evaluate quality and functionality. The overall mean MARS score averaged between the 2 raters was 4.21/5 (SD 0.53), with the following scores for each subcategory: engagement 4.40/5 (SD 0.57), functionality 4.13/5 (SD 0.18), aesthetics 4.17/5 (SD 0.71), information 4.33/5 (SD 0.47), and subjective quality 4.0/5 (SD 0.71). However, interrater reliability, as measured by CA-ICC, was poor (0.348). The mean SUS score was 92.5/100 (SD 10.6), with an excellent CA-ICC of 0.912. The IMS score was 6.5 (SD 0.7) of the 11 recommended functions. Functions that both reviewers found to be missing were the ability to share and evaluate data, the provision of guidance based on user-entered information, and the provision of communication between health professionals and patients.

Next, Attuned was assessed with regard to health literacy via the CDC, IOM, and PEMAT scales. The CDC Clear Communication Index was 82.5% (SD 24.7 percentage points), slightly below the recommended "passing" score of 90%; missing elements largely pertained to the use of language, which is likely to be used by the audience, and to the use of chunked or bulleted text. The CA-ICC for this measure was also poor (0.347). The mean IOM score was 28.5 (SD 2.1) of 33

XSL•FO
RenderX

recommended strategies implemented within Attuned, with the "engage users" and "evaluate and revise your site" domains scoring lower. Both PEMAT actionability and understandability scores were 100%, with complete agreement between reviewers with a CA-ICC of 1.00.

Readability as determined by the Flesch-Kincaid Reading Level and the Gunning Fog Index scores was 5.6 and 7.9, respectively, both below the recommended eighth-grade reading level. The Flesch Reading Ease was 72.3, corresponding to roughly a seventh-grade reading level. However, the SMOG index was 9.3, signifying that 9.3 years of school education would be necessary to read the text, and the Coleman-Liau index also resulted in an eighth-grade reading level at 8.7. On the other hand, the New Dale-Chall score was 4.5, roughly corresponding to a fourth-grade reading level.

Integration of Qualitative and Quantitative Findings

Qualitative and quantitative findings were integrated through narrative comparison and demonstrated substantial convergence. The high SUS score (92.5/100) converged with participants' qualitative descriptions of the app as clear, well-structured, and easy to navigate (Theme 6). The IMS functionality assessment identified missing functions, such as provision of guidance based on user-entered information and communication between users and professionals, that mirrored the qualitative limitation theme of absent feedback and personalization (Theme 8). Similarly, the CDC Clear Communication Index fell below the passing threshold primarily on use of the audience's own language, converging with participants' requests for trans voices and greater dialect diversity in instructional content. Divergence was minimal: the strong PEMAT and readability results were consistent with participants' descriptions of content as "digestible and easy to understand."

Discussion

Principal Findings

In this mixed methods study, we have used qualitative methodology to (1) describe baseline attitudes toward voice and vocal modification among transgender individuals and (2) evaluate impressions of a free mobile app delivering clinically informed GAVT. We have also used a wide variety of validated mHealth-focused scales to assess the mobile app for functionality, usability, health literacy, and readability. Given the increasing focus on gender-affirming health care in the United States, the importance of both research on gender affirmation and easily accessible health interventions for TGNC individuals cannot be overstated. The findings of this study help to further establish the widespread demand and need for GAVT and to understand diverse user experiences with an initial iteration of an open-access novel GAVT mobile app for planned further improvement.

GAVT alone or in combination with surgery has been repeatedly shown to improve objective measures such as fundamental frequency, listener perceptions, and patient-reported outcome measures [45-47]. However, the vast majority of existing evidence is for voice feminization, since exogenous testosterone lowers vocal pitch among transmasculine individuals taking gender-affirming hormones, though many such individuals still report voice problems or dissatisfaction with their voices [48,49]. In addition, compared to the growing quantitative literature, relatively few qualitative studies have been undertaken to deepen understanding of factors affecting patients that are not adequately reflected in quantitative measures.

Our study uncovered several key themes among our study population at baseline, prior to use of the Attuned app. Participants consistently emphasized the importance of their voices as a key facet of their complete gender identity and as a determinant of their ability to be perceived by others in line with their gender. This is in line with prior qualitative studies of both transfeminine and transmasculine individuals, which have identified both internal self-confidence and experiences of misgendering as intimately linked to the voice [50-52]. An additional qualitative study by Holmberg et al [53] also noted the key contributions of the voice toward dysphoria, similar to our findings; although they did not explicitly explore dissatisfaction with the voice in parallel, they also identified a strong motivation among their participants to seek voice modification. Importantly, our inclusion of transgender men and nonbinary individuals alongside transgender women in our study population allowed for key perspectives regarding both trepidation and relative dissatisfaction with certain aspects of testosterone's effects on the voice, highlighting that testosterone alone is sometimes insufficient for achieving vocal congruence. This solidifies the importance of further study among individuals seeking voice masculinization and further use of GAVT among this population. The phenomenon of an outwardly evident "trans guy kind of voice" that can present barriers to "passing" for transgender men is in line with existing knowledge that gender perception goes beyond simple pitch changes. A small number of previous qualitative studies have also raised similar concerns among transgender men who remain dissatisfied or continue to experience misgendering even after long-term testosterone use [52,54]. Furthermore, several nonbinary participants explicitly refrained from a binary feminization/masculinization framing of voice goals, describing both voice coaching and existing apps as engaging in "gender-boxing" that rendered them unusable (Q55, Q74). This underscores that voice modification goals cannot be inferred from gender identity alone and that both GAVT services and mHealth tools should accommodate individualized, nonbinary voice targets.

Contrary to most existing voice-related qualitative research among TGNC individuals, our study population consisted largely of individuals who desired but did not feel that they had access to GAVT. Our cohort also included individuals across a wide range of gender identities, geographic locations, ages, and prior experiences with various gender-affirming treatments. This allowed for substantial exploration of several areas that are not robustly represented in existing literature. For example, our findings regarding self-guided attempts at voice modification, including some practices that participants themselves worried could be causing vocal injury, offer an important glimpse into the vocal practices of TGNC individuals in a landscape of formal GAVT being inaccessible to many. Our findings regarding the importance of context in determining voice use and attempts at voice modification were in line with

XSL•FO
RenderX

prior research [52]. Furthermore, our study uncovered not only themes regarding the inaccessibility of formal voice training but also several patterns of frustration with both publicly available online materials and prior voice-centered mobile apps, which substantially builds on prior work by Bush et al [55]. This represents a shortcoming of prior qualitative research in this field, which has largely recruited individuals already presenting to SLPs for GAVT, thus failing to capture the broad swath of the TGNC population who do not reach this point due to previously mentioned substantial barriers.

Our results also represent a largely positive reception among the first cohort of target users of Attuned from diverse geography, age groups, and gender identities. These results should be interpreted in light of the risk of acquiescence bias, given the interviewers' membership in the development team, and are best understood as encouraging formative feedback rather than evidence of effectiveness. Despite technical glitches in the initial version of the app, participants looked favorably on the app's content, structure, and tools to support their voice modification efforts. Participants emphasized the empowering nature of receiving detailed information about the mechanics of the voice and gender perception, in line with prior qualitative studies of individuals who have undergone GAVT [56,57]. Of note, qualitative literature investigating outcomes of GAVT is remarkably sparse, despite known shortcomings of quantitative measurements in this realm, such as lack of correlation between different patient-reported outcome measures or between these measures and objective acoustic outcomes [5,14]. This suggests that existing literature may not be adequately capturing the full depth of TGNC individuals' experiences with GAVT and identifies a crucial area for further investigation.

Our study also uncovered substantial shortcomings of an app-based delivery of voice training, most prominently the lack of feedback and personalization. While certain aspects of these limitations will be intrinsic to any mobile app, advances in AI and biofeedback may allow future versions of Attuned to respond more robustly in real-time to users [58]. An additional consideration for app-based GAVT is the absence of clinical screening prior to training. In many institutional settings, laryngoscopic examination is recommended before initiating voice training to exclude underlying laryngeal pathology, whereas mobile apps are by nature accessible without professional evaluation. Attuned addresses this in part through an in-app disclaimer encouraging users with voice symptoms to seek evaluation by an otolaryngologist. Moreover, our qualitative findings suggest that in the current landscape, many TGNC individuals without access to formal care already attempt self-guided voice modification using unstructured online resources (including practices participants themselves worried could cause vocal injury). Structured, professionally designed guidance with appropriate safety recommendations may therefore represent a safer alternative to the unstructured resources many users currently rely on. It is also important to note that while some mobile apps focused on GAVT exist, most existing offerings range from free pitch-tracking with limited instructional material to structured instructional content available by subscription only [58-63]. TruVox (University of Cincinnati), a free web-based application, provides real-time pitch and resonance feedback alongside instructional content [58]. To the authors' knowledge, Attuned is distinctive in combining a free sequential video curriculum narrated by voice clinicians with practice assignments and pitch-tracking in a native mobile app developed with a CAB.

With regard to the objective assessment of Attuned, scores on the battery of validated scales were high across quality, functionality, health literacy, and readability, though these tests were performed by members of the authorship team and should be interpreted accordingly. Attuned exceeded the previously published means of laryngology-focused mobile apps across all evaluated scales, notably achieving above 4/5 on the MARS scale and all associated subcategories, 100% on the PEMAT actionability and understandability scales, and resulting in scores below the benchmark of an eighth-grade reading level for the majority of readability scales [21]. Of note, our prior systematic assessment of laryngology mobile apps [21] did not use the SUS; however, Attuned's score of 92.5 was well above the previously reported benchmarks of 68 and 80 across all digital health tools [64]. This reflects the goal of our app design and content creation process to develop a tool that would be readily available to users from around the country and with varying educational and socioeconomic backgrounds [22]. In addition, it should be noted that the version of the app subject to evaluation on these scales was the first version of the app ever made available and contained known glitches and deficits, which have already been targeted for improvement in future iterations. Future iterations of Attuned addressing these known deficits may perform differently, which will require further evaluation.

Despite its novel contributions, this study is not without limitation. First, while TGNC community members were intimately involved in the creation of Attuned and early plans for the qualitative portion of this study, we did not follow a strict community-based participatory research methodology without a governance structure, authorship opportunities, and fair compensation as previously described [22]. Given our group's aspirations toward true community-based participatory research [22], this represents a crucial area of improvement for future studies of Attuned. A new CAB is currently being assembled to guide the revision process of the app, as well as to participate as co-investigators in future prospective research using Attuned.

While our use of semistructured interviews allowed deeper exploration of important themes, the necessary trade-off is that interviews were slightly different from each other and could not be directly compared. In addition, participants may have been subject to acquiescence bias, particularly in the post-Attuned interviews, whereby individuals may have felt subtle pressure to overemphasize positive attitudes toward Attuned, knowing that the interviewers were part of the app's development team. We sought to partially mitigate this bias by asking open-ended questions to signal openness to any opinions that participants would share. Additionally, the objective assessment scales were completed by 2 authors. Although they were not involved in the app's development, they were not independent of the study team, and these ratings therefore cannot be regarded as fully unbiased. Usability measures were not collected directly from study participants, which we have

XSL•FO
RenderX

incorporated into the design of our planned prospective follow-up study. Furthermore, we did not apply exclusion criteria to potential participants (aside from requiring that they were identified within the TGNC umbrella). Our study may therefore be limited by selection bias, as participants choosing to participate in a study of GAVT are likely already interested in GAVT and are also highly motivated to pursue it; our study population—despite our best efforts to recruit broadly from across the country and to include a variety of gender identities and socioeconomic statuses—may thus have limited generalizability to the population of TGNC individuals at large. Participants' specific voice modification goals (feminization, masculinization, androgynous, or other targets) were not captured as a survey item. Although gender identity distribution offers an approximation, these do not map neatly onto one another, and explicit characterization of voice goals will be incorporated into future studies. Our study did not collect backend information regarding each participant's usage pattern or time spent on the app, which may have allowed for deeper analysis of participants' impressions of the app. Finally, both interviewers are cisgender men and members of the LGBTQ+ community but not the TGNC community; this positionality, as previously mentioned, may have impacted the responses of some participants, who may have responded differently to non-LGBTQ+ interviewers or fellow TGNC individuals.

Future directions for our team include 2 directions. First, a revision of the Attuned app based on our participants' feedback is currently underway, guided by a newly assembled CAB and addressing the technical issues identified in this study and expanding the diversity of voices represented in the instructional content. Planned future capabilities include personalized AI-driven guidance and real-time voice biofeedback to address the feedback and personalization limitations identified by participants, with development contingent on available funding and technical resources. Our team also plans a prospective, quantitative assessment of the app's efficacy, including participant-administered usability measures, as compared with standard-of-care in-person GAVT. The present study also highlighted several important future directions for the field, including prioritization of studies of transgender men or other individuals seeking voice masculinization, outreach to populations without access to traditional GAVT, and expansion of overall qualitative study of TGNC individuals either seeking or after voice modification training in order to identify shortcomings and further improve outcomes for these individuals.

Conclusion

The voice is a crucial part of identity and interpersonal interactions for TGNC individuals, and many desire tools for voice modification but have difficulty accessing high-quality GAVT. In a landscape full of unstructured free resources of varying levels of trustworthiness, there is a critical unmet need for a structured, clinically informed curriculum that can be accessible at scale. Attuned, a free mobile app developed through a user-centered approach, was positively received by an initial cohort of TGNC users. While app-based training cannot replace the individualized feedback of one-on-one voice training, these findings suggest promise in expanding access to structured, professionally developed GAVT, to be confirmed in a prospective comparative study.

Abstract

Background: Family caregivers of children with disabilities frequently experience high levels of stress and psychological burden. Digital support platforms offer accessible channels for information and emotional support, but their long-term use patterns remain underexplored.

Objective: This study explored the longitudinal patterns of digital support platform use among family caregivers in China, with a focus on factors potentially associated with initial adoption and continued engagement.

Methods: A 3-wave survey was conducted over 6 months with 240 primary caregivers of children with disabilities in China. A 2-part latent growth curve model was used to jointly model adoption (use vs nonuse) and engagement (use frequency among users). Key demographic, psychosocial, and child-related factors were examined as predictors.

Results: Adoption increased significantly over time (probit slope=0.54, SE 0.16; *P*=.001). Higher baseline adoption was associated with male sex (β=.19; *P*=.02), higher education (β=.42; *P*<.001), better socioeconomic status (β=.26; *P*=.001), stronger social support (β=.17; *P*=.03), and more depressive symptoms (β=.18; *P*=.02). Among users, engagement frequency showed no significant average change over time (mean slope=–0.07, SE 0.07; *P*=.31). Higher initial engagement was associated with higher education (β=.36; *P*<.001) and social support (β=.20; *P*=.04). Better child rehabilitation status was associated with steeper declines in engagement over time (β=–.28; *P*=.03).

Conclusions: Adoption and engagement showed distinct longitudinal patterns and were associated with different factors. The findings suggest that reducing digital barriers and aligning support with caregivers' evolving needs may be relevant to facilitating platform use and sustained engagement. This study offers a theory-informed lens for describing digital support platform use among vulnerable caregiving populations.

digital support; family caregivers; children with disabilities; adoption; engagement

Introduction

Background

Amid rapid digitalization, family caregivers of children with disabilities are increasingly seeking support online. Substantial evidence shows high caregiving stress and poor mental health outcomes in this population [1-3]. Caregivers need reliable information about rehabilitation services, special education, and policy, as well as emotional understanding and support. However, limited professional resources and disability-related stigma often constrain offline help seeking. In this context, digital support platforms (eg, peer forums, social media groups, and specialized online communities) offer scalable, low-cost channels for information exchange and emotional support, often with anonymity [4].

While digital platforms have been shown to enhance perceived social support and improve caregiver well-being [4,5], most evidence is cross-sectional or intervention-specific. Less is known about how routine platform use changes over time and whether determinants differ for adoption vs engagement. Addressing these gaps is important for theory—clarifying how vulnerable populations engage with digital health resources—and for practice—informing design and policy that foster equitable and sustained engagement.

Use of Digital Support Platforms Among Caregivers of Children With Disabilities

Caregivers commonly use digital platforms for 2 core functions. First, information seeking: they look for practical guidance on condition management, rehabilitation options, and special education to address day-to-day challenges [6]. Second, social and emotional support: platforms connect families facing similar circumstances, facilitating experience sharing and mutual understanding that can alleviate isolation [7,8]. Qualitative evidence indicates that platforms aligning with both informational and emotional needs foster more positive engagement [9].

Evidence for benefits spans unstructured communities and structured programs. Open online communities have been associated with higher perceived social support and lower stress levels among parents of children with autism [8]. Structured interventions (eg, CaregiverTLC) can strengthen self-efficacy and coping capacity [10,11]. Reviews suggest that peer support networks may serve as a pathway to strengthening family caregivers and fostering their resilience [12]. Studies also point to potential compensatory effects, with more diverse, supportive networks linked to lower major depression risk [13].

Factors Associated With the Use of Digital Support Platforms

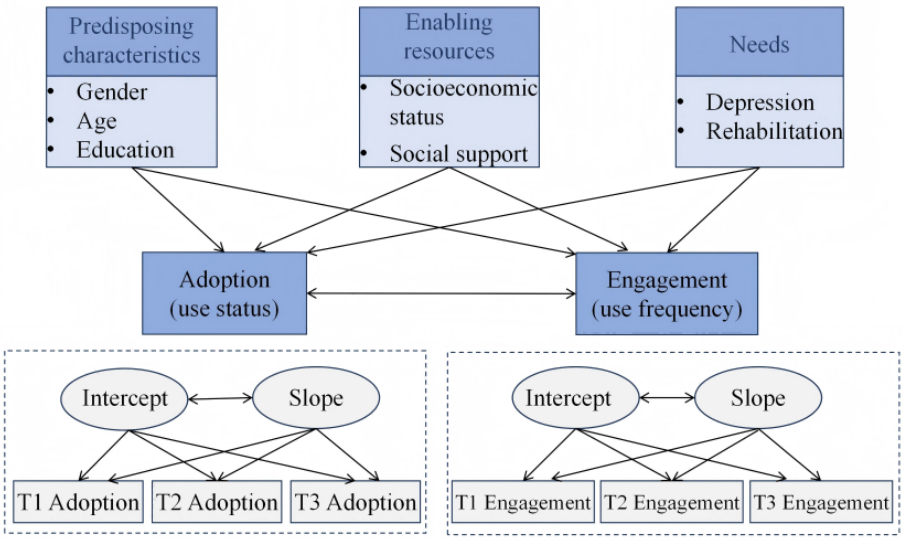
Caregivers' digital platform use can be understood through Andersen's behavioral model of health services use (BMHSU), which categorizes determinants into 3 domains: predisposing characteristics, enabling resources, and needs [14]. Predisposing characteristics (eg, age, gender, and education) reflect general propensities to use services. Enabling resources (eg, socioeconomic conditions, social support, and access to devices or connectivity) shape the practical feasibility of use. Needs, both perceived by individuals and evaluated by professionals, are the most proximal drivers of use. The model has demonstrated utility across traditional health services and increasingly in digital health contexts [15-17].

For caregivers, 3 key factors emerge. First, predisposing characteristics matter. Higher educational attainment is generally associated with greater use for accessing and sharing health information, while older age, lower education, and limited language proficiency are linked to barriers such as lower digital literacy and reduced access [18-21]. Gender differences in engagement remain unclear, as studies often overrepresent mothers and reflect caregiving roles [4,20].

Second, enabling resources are pivotal. Socioeconomic status—income, employment, and access to devices and connectivity—conditions capacity to engage and shapes use patterns [22]. Contextual enabling conditions, including credible information and robust privacy protections, can lower perceived risk; caregivers often prefer closed groups to safeguard privacy [23,24]. Social support further enables platform use by providing informational, emotional, and practical assistance, which helps caregivers navigate digital tools and sustains engagement [25,26].

Third, needs are immediate drivers of use. Psychological distress often drives online support seeking, with higher depressive symptoms linked to greater pursuit of emotional support [27-29]. Children's health and rehabilitation status represent key evaluated needs that sustain information seeking and support seeking over time. Even after receiving a diagnosis, many parents continue to consult multiple sources for condition details, prognosis, and management strategies, highlighting the persistent role of clinical needs in motivating digital engagement [30].

The Present Study



Despite growing interest in caregivers' use of digital support platforms, the literature is dominated by cross-sectional designs and short-term intervention evaluations that seldom track routine, real-world use over time. Consequently, evidence on sustained use beyond program contexts remains limited. Prior work rarely distinguishes whether caregivers use a platform (adoption) from how often they participate among users (engagement). Conflating these processes introduces zero-inflation concerns and may obscure distinct trajectories and determinants.

To address these gaps, we conducted a 3-wave, 6-month longitudinal study of 240 family caregivers of children with disabilities in China. We used a 2-part latent growth curve model to jointly estimate adoption (use vs nonuse) and engagement (frequency among users) trajectories [31,32]. This approach accommodates zero-inflated, semicontinuous data and enables direct comparison of predictors across processes.

Guided by the BMHSU [14] and tailored to the caregiving context, we examined predictors in 3 domains: predisposing characteristics (caregiver gender, age, and education), enabling resources (socioeconomic status and social support), and needs (caregivers' depressive symptoms as perceived need; children's rehabilitation status as evaluated need). The conceptual framework is presented in Figure 1.

XSL•FO
RenderX

Figure 1. Conceptual framework of the study.

We hypothesized that both adoption probability and engagement would increase over time (hypothesis 1), there would be significant interindividual variability in the initial levels and growth trajectories of both adoption and engagement (hypothesis 2), and predictors would differentially relate to adoption vs engagement (hypothesis 3).

Methods

Study Design

This study used a prospective longitudinal design with 3 survey waves. Digital support platform use was repeatedly measured at each wave using a 3-month recall window aligned with the interwave interval. All other predictors, including demographics and psychosocial variables, were assessed at baseline and used in analyses as predictors.

Participants

The inclusion criteria were as follows: (1) being the primary family caregiver (ie, the adult most responsible for the child's daily care and health decisions) of a child or adolescent aged ≤18 years with a confirmed disability diagnosis, (2) ability to complete an online smartphone survey, and (3) provision of electronic informed consent. The exclusion criteria were as follows: (1) severe cognitive or communication barriers precluding survey completion and (2) duplicate entries within the same household (1 caregiver per child).

We recruited caregivers from rehabilitation centers, special education schools, and hospitals in Sichuan, Chongqing, and Shandong, China. A total of 485 valid wave 1 responses were obtained; 259 (53.4%) caregivers consented to be recontacted. Of these, 199 and 191 valid responses were collected at waves 2 and 3, respectively. The longitudinal analytic sample comprised 240 caregivers who completed at least 1 follow-up wave. Because recruitment relied on convenience sampling via advertisements and voluntary self-registration, the number of individuals who were exposed to the recruitment materials or invited to participate was not available; therefore, a formal response rate could not be calculated.

Participant characteristics were as follows: 29% (70/240) were male, with a mean age of 37.29 (SD 6.85) years. Most (215/240, 89.6%) had completed junior high school or higher, and 33% (78/240) held a bachelor's degree or above. Subjective socioeconomic status was rated as average or below by 86.3% (207/240). The most common child disabilities were intellectual (65/240, 27%) and psychiatric (51/240, 21%). Rehabilitation status was mostly rated as fair or good (174/240, 72.7%). Additional details are presented in Table S1 in Multimedia Appendix 1.

Measures

Digital Support Platform Use

A study-developed measure assessed digital support platform use, informed by prior interviews with family caregivers to ensure cultural relevance and alignment with common platform formats. The questionnaire was reviewed by 2 subject matter experts before data collection. To reduce recall bias, respondents reported their platform use over the past 3 months, with descriptions and examples provided for each platform type. Participants indicated how often they used disability-focused digital support platforms (eg, service portals, live streams, chat rooms, social media groups, and online forums) in the past 3 months. Responses were coded as 0=never, 1=rarely (eg, less than once per month), 2=occasionally (eg, 1‐3 times per month), 3=often (eg, 1‐3 times per week), and 4=almost daily (eg, 4 or more times per week). Platform adoption was coded as 0=nonuse and 1=any use (responses 1‐4), while engagement was modeled as the frequency of use among users (responses

XSL•FO
RenderX

1 - 4). Nonusers were asked to report reasons for nonuse, including lack of time, unawareness, unfamiliarity, privacy concerns, or other (open ended).

Social Support

Perceived social support was measured at baseline using the 12-item Social Support Scale [33], which assesses family, friend, and other support. Items are rated on a 7-point scale (1=strongly disagree to 7=strongly agree). According to the scoring criteria in the original guidance, total scores of 12 to 36, 37 to 60, and 61 to 84 indicate low, moderate, and high support, respectively. In the present study, the Cronbach α for the scale was 0.92.

Depression

Depressive symptoms were measured at baseline with the Chinese version of the 9-item Patient Health Questionnaire [34,35]. The scale consists of 9 items rated on a 4-point scale (0=not at all to 3=nearly every day). Scores of 5, 10, 15, and 20 correspond to the cutoff points for mild, moderate, moderately severe, and severe depressive symptoms, respectively. The Chinese version of this scale has been previously validated in a sample of parents of children with disabilities in China [36]. In the present study, the Cronbach α for the scale was 0.94.

Demographic Characteristics

Demographic characteristics were collected at baseline for both the child and the caregiver. Child factors included the primary disability type (visual, hearing, physical, speech, intellectual, psychiatric, or multiple) and current rehabilitation status rated on a 5-point scale (1=extremely poor to 5=excellent). Caregiver factors included gender, age, education, and subjective socioeconomic status, obtained via a structured questionnaire.

Ethical Considerations

This study adhered to the ethical principles of the Declaration of Helsinki and was approved by the Academic Committee of Southwest Minzu University (SMU-202401037). All participants provided electronic informed consent prior to participation.

Procedures

The study was conducted from September 2024 to July 2025, with 3 waves of data collection at 3-month intervals. Participants were recruited through collaborating schools, hospitals, and rehabilitation centers in Sichuan Province, Chongqing Municipality, and Shandong Province. These institutions distributed posters advertising the study, and interested caregivers of children with disabilities voluntarily registered by scanning a QR code. Eligible participants who provided informed consent were invited to complete a 10-minute online survey for each wave. To prevent duplicate submissions, IP-based restrictions were implemented, and surveys completed in unrealistically short times were excluded as invalid. Follow-up surveys were distributed 3 months after the participants' initial survey date. As an incentive, participants received CNY 10 (CNY 1=US $0.15 as of September 5, 2026) for each completed wave.

Data Analysis

Analyses included participants who completed the baseline and at least 1 follow-up assessment (n=240). To examine selective attrition, baseline characteristics were compared between participants retained for longitudinal analyses and those lost to follow-up. No significant differences were found in platform use (χ^2_4=7.5; *P*=.11), age (t_{483}=0.57; *P*=.57), education (χ^2_5=5.6; *P*=.35), subjective socioeconomic status (χ^2_4=5.3; *P*=.26), disability type (χ^2_6=9.9; *P*=.13), child rehabilitation status (χ^2_4=8.2; *P*=.08), or depression (t_{483}=–1.20; *P*=.23). However, the attrition group had a higher proportion of men (χ^2_1=7.2; *P*<.01) and higher social support (t_{483}=3.97; *P*<.001). Overall, selective attrition appeared modest: most baseline characteristics did not differ, although men and those with higher social support were more likely to drop out. Missing data were handled using full information maximum likelihood (FIML).

Descriptive statistics and bivariate correlations were computed for key variables. Core analyses used a 3-wave, 2-part latent growth curve model (time coded as 0, 1, and 2) to decompose platform behavior into two components: (1) adoption (any use vs nonuse; categorical probit specification; latent intercept I_B and slope S_B) and (2) engagement (use frequency among users; measured on a 4-level ordinal scale treated as continuous in the primary model; latent intercept I_C and slope S_C). Random intercepts and slopes were allowed to covary within and across components to account for shared determinants and correlated dynamics. Engagement was reestimated as ordinal for robustness, yielding consistent results.

Unconditional models were first estimated to assess mean trajectories and variance components. Covariates (gender, age, education, socioeconomic status, social support, depressive symptoms, and child rehabilitation status) were then added to predict the 4 growth factors. All models used maximum likelihood estimation with robust standard errors in Mplus (version 7.4; Muthén & Muthén). Model fit was evaluated using chi-square statistics, Akaike information criterion (AIC), Bayesian information criterion (BIC), and sample size–adjusted BIC. Robustness checks were performed by reestimating the model with the full baseline sample (n=485) using FIML to handle longitudinal missingness across waves.

Results

Digital Platform Use Among Caregivers Across 3 Waves

Across 3 waves, caregivers reported how often they had used any disability-related digital platform in the past 3 months; nonusers additionally selected one or more reasons for nonuse. Table 1 presents the distributions of use frequency and reasons for nonuse at each wave.

XSL•FO
RenderX

Table . The use of disability-related digital platforms among caregivers.[a]

	T1[b], n (%)	T2[b], n (%)	T3[b], n (%)
Use frequency			
Never	65 (27)	47 (24)	27 (14)
Rarely	23 (10)	16 (8)	19 (10)
Occasionally	56 (23)	44 (22)	54 (28)
Often	58 (24)	66 (33)	65 (35)
Almost daily	38 (16)	26 (13)	26 (13)
Reasons for nonuse			
Limited time or energy	22 (34)	13 (28)	6 (24)
Unaware of platform availability	40 (62)	20 (44)	7 (28)
Unfamiliar with how to use platforms	4 (6)	15 (33)	10 (40)
Concerns about cybersecurity or privacy	6 (9)	10 (22)	1 (4)

[a]Percentages are based on respondents with nonmissing data at each wave. Nonuse reasons were multiple response items.

[b]T1 represents the first measurement, T2 represents the second measurement, and T3 represents the third measurement.

Descriptively, the share of caregivers reporting any use increased over time, reflected in a decline in "Never" from 27% (65/240) to 14% (27/191). The distribution also shifted toward midrange categories ("Occasionally" and "Often"), whereas the proportion reporting "Almost daily" was relatively stable, with a slight decrease from T1 to T3.

Regarding nonuse, lack of awareness of platform availability and limited time or energy were the most frequently cited barriers at T1. Over time, reports of awareness and time or energy barriers declined, whereas unfamiliarity with how to use platforms increased, suggesting a shift from access or awareness constraints toward competence-related barriers. Cybersecurity or privacy concerns peaked at T2 and declined at T3.

Descriptive Statistics and Correlations

Descriptive statistics and bivariate associations among study variables across the 3 waves are summarized in Table 2. Spearman rank correlations were used to accommodate ordinal scaling and potential nonnormality. Platform-use categories exhibited moderate temporal stability, and associations with covariates varied in magnitude and direction.

Two-Part Latent Growth Analysis of Digital Platform Use and Predictors

To distinguish between adoption and engagement intensity, platform use was modeled using a 2-part latent growth curve model. The binary component represented use status at each wave (b1-b3), while the continuous component captured use frequency among users (c1-c3). Unconditional growth models were first estimated separately for each part and then combined in a parallel 2-part model. In preliminary analyses, allowing the adoption slope variance (S_B) to be freely estimated resulted in numerical instability and nonconvergence, indicating insufficient information to reliably estimate between-person variability in change in the 3-wave binary adoption process. Therefore, in the primary models, we fixed Var(S_B)=0, retained a random intercept for adoption, and estimated the mean adoption slope to characterize the average change in adoption over time. The unconditional 2-part model showed acceptable fit (Pearson χ^2_4=2.2, *P*=.69; likelihood ratio χ^2_4=2.4, *P*=.67; AIC=1805.95; BIC=1851.19; adjusted BIC=1809.99).

We then estimated a conditional 2-part model incorporating gender, age, education, socioeconomic status, child rehabilitation status, social support, and caregiver depressive symptoms. Compared with the unconditional model, the conditional model showed lower AIC (1736.54 vs 1805.95) and sample size–adjusted BIC (1747.11 vs 1809.99), although BIC increased slightly (1854.88 vs 1851.19). Given the a priori inclusion of covariates and overall model performance, we retained the conditional model for inference.

In the binary part, the mean slope was positive (S_B=0.54, SE 0.16; *P*=.001), indicating increasing probability of adoption over time; the intercept variance was significant (Var(I_B)=2.76, SE 0.82; *P*=.001), evidencing substantial heterogeneity at baseline. In the continuous part, the mean intercept indicated relatively high initial frequency among users with significant between-person variability (I_C=2.52, SE 0.10; *P*<.001; and Var(I_C)=0.58, SE 0.14; *P*<.001). The mean slope was not significant (S_C=−0.07, SE 0.07; *P*=.31), but its variance approached significance (Var(S_C)=0.11, SE 0.06; *P*=.07), indicating variability in individual change rates. A strong negative correlation between the intercept and slope (*r*=−0.72; *P*<.001) suggested that users with higher initial use frequency tended to show flatter or declining trajectories over time.

Covariate effects indicated that education was a robust positive correlate of baseline adoption, with additional positive associations for socioeconomic status, social support, depressive symptoms, and male gender. For initial use frequency among users, education and social support were positive predictors, whereas other effects were small and nonsignificant. Regarding change in frequency, better child rehabilitation status predicted steeper declines over time. Parameter estimates are presented in Tables 3 and 4.

Table . Estimated means and variances of growth factors in the 2-part latent growth curve model.[a]

Latent factor	Growth factors, mean (SE)	*P* value	Growth factors, variance (SE)	*P* value
Use status intercept (I_B)	N/A[b]	N/A	2.76 (0.82)	.001
Use status slope (S_B)	0.54 (0.16)	.001	0 (fixed)	N/A
Use frequency intercept (I_C)	2.52 (0.10)	<.001	0.58 (0.14)	<.001
Use frequency slope (S_C)	−0.07 (0.07)	.31	0.11 (0.06)	.07

[a]The variance of S_B was fixed to zero due to numerical instability and nonconvergence when freely estimated. The mean of I_B is not separately estimated under the categorical (threshold or latent response, probit) parameterization.

[b]N/A: not applicable.

Table . Predictors of adoption intercept and engagement growth factors.[a]

Predictor	Adoption intercept I_B, β (SE)	*P* value	Engagement intercept I_C, β (SE)	*P* value	Engagement slope S_C, β (SE)	*P* value
Gender	0.19 (0.08)	.02	−0.04 (0.08)	.68	0.12 (0.12)	.34
Age (z-score)	−0.11 (0.07)	.11	0.00 (0.08)	.96	−0.12 (0.14)	.37
Education (z)	0.42 (0.08)	<.001	0.36 (0.10)	<.001	0.04 (0.15)	.78
Socioeconomic status (z)	0.26 (0.08)	.001	0.11 (0.09)	.21	−0.05 (0.14)	.69
Rehabilitation (z)	−0.08 (0.09)	.37	0.13 (0.08)	.10	−0.28 (0.13)	.03
Social support (z)	0.17 (0.08)	.03	0.20 (0.10)	.04	−0.09 (0.15)	.55
Depression (z)	0.18 (0.08)	.02	0.08 (0.08)	.31	−0.02 (0.12)	.89

[a]Standardized coefficients (β) with SEs and *P* values. IB uses a categorical probit specification. SB was not regressed on covariates because Var(S_B) was fixed to 0.

As a sensitivity analysis, we reestimated the 2-part model with the full baseline sample (n=485) using FIML to handle longitudinal missingness across waves. Results were largely consistent with the primary analysis, supporting the robustness of the main conclusions. Caregiver age became a significant predictor of baseline adoption in the full baseline sample, whereas the rehabilitation–engagement growth association was attenuated to a marginal level (directionally consistent). Detailed estimates are provided in Tables S2 and S3 in Multimedia Appendices 2 and 3, respectively.

Discussion

This study used a 2-part latent growth curve model to explore the dynamics and potential predictors of digital support platform use among family caregivers of children with disabilities. Findings indicated that platform adoption increased over time, while average engagement remained stable. Distinct predictors for adoption and engagement may reflect differing processes underlying initial uptake vs sustained participation.

Status and Trajectory of Digital Platform Use

At the adoption level, the positive mean slope in the binary part suggests an increasing probability of platform use over time, with adoption becoming more common. This increase may reflect the growing availability of online resources and broader shifts toward digital help seeking [37]. Notably, the slope variance (S_B) was not stably estimable and was therefore fixed to zero. Consequently, between-person variability in adoption change over time was not modeled, which may underestimate heterogeneity in adoption trajectories.

A different pattern emerged for engagement frequency. Baseline engagement frequency (I_C) showed significant between-person variability, while the mean slope (S_C) was near zero, indicating stable average engagement at the group level. Evidence for variability in S_C was marginal, suggesting some heterogeneity in individual trajectories. The negative correlation between I_C and S_C suggests differing trends by initial engagement level, possibly reflecting needs-based adjustment, regression to the mean, or ceiling effects.

Factors Associated With Digital Support Platform Use Among Caregivers

Guided by the Andersen BMHSU [14], we examined predisposing (gender, age, and education), enabling (subjective socioeconomic status and social support), and need-related (child rehabilitation status and depressive symptoms) factors.

For adoption, education emerged as a robust positive correlate, consistent with evidence linking higher educational attainment to digital literacy and earlier uptake [20]. Subjective socioeconomic status was also positively associated with adoption, aligning with research highlighting the role of digital capital and reduced barriers among higher-status groups [26,38]. Social support was another significant predictor, indicating that richer offline networks may facilitate online navigation [25]. Depressive symptoms were positively associated with adoption, supporting the notion of need-driven help-seeking behavior [29].

Interestingly, in this sample, male caregivers had a higher baseline probability of adoption, contrasting with prior studies that often report greater digital use among females [39]. However, this finding may reflect study-specific factors such as caregiver demographics, selection bias, or attrition and should not be overinterpreted as evidence of a stable gender difference. Instead, it highlights the context-dependent nature of gender effects on platform use, which may vary across settings.

For engagement frequency, only education and social support predicted baseline levels, suggesting that engagement is more closely tied to competencies and social resources than to other sociodemographic characteristics. Changes in engagement frequency were most consistently related to child rehabilitation status: better rehabilitation outcomes tended to coincide with steeper declines in use, consistent with Andersen's premise that lower perceived need is linked to reduced use [14,16]. However, this association was attenuated to a marginal level in the full baseline sample, and alternative explanations (eg, unmet evolving needs among families with improving outcomes) should be considered.

Overall, the findings partially support Andersen's model for understanding caregivers' digital platform use. At the same time, digital health use often unfolds in 2 stages—adoption and

XSL•FO
RenderX

engagement—and may also depend on technology-specific mechanisms. The technology acceptance model (TAM) and unified theory of acceptance and use of technology (UTAUT) emphasize perceived usefulness, ease of use, and facilitating conditions (eg, skills, support, and resources) [40,41], while privacy-trust research highlights privacy risk appraisal and trust [42]. Although we did not directly measure these constructs, descriptively reported barriers changed over time: "lack of awareness" declined from T1 to T3, "not knowing how to use" increased, and privacy concerns peaked at T2 but declined by T3. These patterns suggest that integrating TAM or UTAUT and privacy-trust constructs with Andersen's framework may better capture the dynamics of adoption and sustained engagement in digital health contexts.

Practical Implications

On the basis of these findings, several practical implications emerge. To support adoption and reduce inequities, interventions may prioritize caregivers with lower educational attainment, socioeconomic status, and social support. Simplified onboarding delivered through community networks, schools, and rehabilitation centers may lower entry barriers, and brief digital literacy training could address capability gaps. Targeted awareness campaigns may further promote adoption. Because adoption was higher among caregivers reporting more depressive symptoms, onboarding should also include clear pathways to emotional and psychological support, including referral options.

To support sustained engagement, digital health platforms should be adaptive, user-friendly, and trustworthy. Given stable average engagement but heterogeneous individual trajectories, personalization can adjust content, peer matching, and support intensity as caregiver needs change [43,44]. AI-based guidance may help reduce information overload and improve perceived usefulness, but implementation requires appropriate governance and safeguards [45,46]. Usability can be strengthened through caregiver-centered interface design [47], and privacy protections with transparent communication are important for maintaining trust [48].

Finally, integrating digital platforms into existing support systems may enhance reach and sustainability. Coordinated efforts across government agencies, social welfare organizations, rehabilitation centers, and special education schools can support promotion, onboarding, linkage to services, and ongoing feedback so that platforms evolve with caregivers' needs.

Limitations

This study has several limitations. First, platform use was measured with a study-specific self-report instrument informed by caregiver interviews and expert review; however, the instrument has not undergone formal psychometric validation, including evaluation of construct validity, criterion validity, and reliability. Engagement was also operationalized only as use frequency, without capturing other dimensions such as session intensity, interaction quality, or emotional engagement. Consequently, qualitatively different use patterns (eg, frequent passive browsing vs infrequent but high-quality interaction) may have been conflated, limiting interpretation of engagement trajectories.

Second, although multicenter recruitment may reduce regional bias, convenience sampling may have favored caregivers with higher needs, limiting representativeness. Differential attrition (with higher dropout among male participants and those with greater baseline social support) may further bias estimates. Attrition also reduced sample size and power for detecting longitudinal effects, so null findings should be interpreted cautiously.

Third, because participants were recruited primarily in China, generalizability to other contexts is uncertain. Cross-country differences in caregiving systems, digital literacy, internet access, and health care infrastructure may shape adoption and engagement.

Finally, although the longitudinal design supports temporal ordering, the study remains observational and measurement reactivity cannot be ruled out; completing baseline assessments may have influenced subsequent platform use. Future studies could lessen potential priming from surveys by shortening assessments and, where possible, supplementing self-report with platform use logs.

Conclusions

This study used a 2-part latent growth curve model to examine digital platform use among caregivers of children with disabilities in China. Adoption increased over time and was positively associated with education, gender, subjective socioeconomic status, social support, and depressive symptoms. Average engagement remained stable, with baseline engagement related to education and social support. Changes in engagement were most consistently associated with child rehabilitation status. Overall, these findings underscore the value of distinguishing adoption from engagement and suggest that caregiver resources and needs are related to patterns of digital platform use.

Abstract

Background: Mobile apps marketed to support mental health have become increasingly popular in recent years. Given their widespread use, it is important to identify issues that users experience while using such apps. Understanding these issues may provide insight into the safety and suitability of these apps for individuals seeking mental health support.

Objective: Unlike existing research, where user experience issues have been identified through researchers' direct analysis of apps, this study aimed to generate themes relating to user experience issues using comments from app users themselves. An additional aim was to evaluate a human-in-the-loop machine learning approach using structural topic modeling (STM) to analyze vast volumes of data gathered from X (formerly Twitter, developed by Twitter, Inc).

Methods: Data relating to five of the most popular mental health apps were collected from the X API using R. A machine-assisted thematic analysis approach combined STM with human qualitative analysis to interpret user-generated posts. An unsupervised topic-modeling approach was tested using models with 5-40 topics and differing covariates (ultimately, a model without covariates was selected). Two researchers independently conducted thematic analysis to interpret and contextualize model outputs. A structural topic model with 10 topics, each comprising 20 X posts, was selected as most appropriate for generating insights.

Results: Using R (developed by the R Core Team), 79,703 X posts were collected via the X API relating to five popular mental health apps. After negative sentiment filtering, 19,603 posts remained. Posts spanned March 2006 (the launch of X/formerly Twitter) to December 2022. Researchers collaboratively labeled the 10 topics to identify the primary user experience issue represented in each. Topic 3 was discarded due to low coherence and inconsistency in relation to app user experience, and Topic 5 was discarded because posts reflected app X account activity rather than user experience of the apps. The remaining eight topics were organized into four themes. The first theme, guidance shortfall, included difficulties following guided meditations, challenges selecting appropriate content from large libraries, and incompatibility between app use and home environments. The second theme, technical difficulties, involved subscription access issues and technical faults within apps. The third theme, heightened emotions related to app-affiliated celebrities, captured both over-excitement linked to celebrity involvement and anger directed toward specific celebrities. The final standalone theme, negative impacts of sleep self-monitoring, demonstrated users reporting that tracking sleep adversely affected sleep experience.

Conclusions: The combination of STM and human qualitative analysis of X posts identified several user-experienced issues associated with popular mental health apps, often linked to negative outcomes. This study provides evidence that STM can be combined with qualitative methods to rapidly analyze large-scale social media data and generate insights into user experience of mass-reach digital health interventions.

Introduction

In England, 1 in 4 people experience mental health issues annually, with 1 in 6 reporting common problems such as anxiety or depression on a weekly basis [1,2]. Depression is the leading global cause of disability [3], and severe mental illness can reduce life expectancy by up to 20 years due to preventable physical conditions [4]. People with poor mental health may feel down, irritable, hopeless, and exhibit behavior changes such as social withdrawal, self-harm, sleep loss, increased use of drugs and alcohol, and altered eating habits [5]. Only

XSL•FO
RenderX

one-third of adults in England and Wales with common mental health conditions receive treatment [2,6], despite the World Health Organization noting globally low treatment rates [4]. Barriers to seeking help include limited knowledge about mental illness, unawareness of treatment options, and fear of stigma [7].

Given the low uptake of formal support, individuals often turn to digital alternatives. The mental health app market, valued at $5.2 billion in 2022, is projected to grow at 18% annually until 2030 [8]. Popular apps such as Calm (developed by Calm.com, Inc), Headspace (developed by Headspace, Inc), and Sleep Cycle (developed by Sleep Cycle AB) offer mindfulness, relaxation, and sleep-related features, with Calm alone exceeding 107 million downloads between 2018 and 2022 [9]. However, concerns remain regarding app effectiveness, as many apps lack empirical support, involve few health care professionals in development, and provide limited or inaccurate tracking of mental health metrics [10-15]. The unregulated nature of this market, coupled with the prioritization of venture capital-driven growth, may contribute to these shortcomings [16-18].

This study is situated within the broader landscape of mobile health (mHealth) apps, a heterogeneous category encompassing digital tools designed to support health and well-being through mobile devices [19]. Within this ecosystem, mental health apps represent a diverse subset that spans multiple functional domains, including mindfulness and meditation, sleep improvement, mood regulation, psychoeducation, and passive or active self-tracking [20]. The five apps analyzed in this study—Calm, Headspace, BetterSleep (developed by Ipnos Software Inc), Sleep Cycle, and Waking Up (developed by Waking Up, LLC)—were selected based on their status as the top-grossing mental health apps in December 2022 [9], reflecting their commercial reach and user uptake rather than functional equivalence. While Calm, Headspace, and Waking Up all foreground guided meditation and mindfulness training as core components of user engagement, they differ notably in content and delivery approaches. Headspace adopts a structured, practical approach designed to make mindfulness accessible and habit-oriented, whereas Waking Up places greater emphasis on deeper philosophical discussions and the scientific underpinnings of consciousness [21,22]. Calm, by contrast, frames mindfulness within a broader relaxation and wellness context that incorporates sleep stories and ambient soundscapes alongside meditation guidance [23]. BetterSleep occupies a hybrid position, combining relaxation, soundscapes, and sleep-focused mindfulness with elements of habit formation, while Sleep Cycle is distinct in its emphasis on sleep tracking, biometric data, and algorithmic analysis, positioning mental well-being primarily through sleep optimization rather than direct psychological intervention [24,25]. These apps therefore differ substantially in their target users, behavioral change strategies, and technological affordances, ranging from content-driven experiential engagement to data-driven self-monitoring. A comparative analysis of these apps enables examination of how varied mHealth design logics, commercial priorities, and conceptualizations of mental health are operationalized within widely adopted platforms, providing insight into the broader mental health app market rather than a single therapeutic modality.

Social media offers a rich and ecologically valid data source for evaluating user experiences of apps. X (formerly Twitter), which allows third-party data access via its API, supports large-scale qualitative research by providing real-world, unsolicited feedback [26,27]. X's arrival in 2006 predates that of any mental health apps by at least 2 years [28-30]. With around 238 million global monthly active users, the real-time and conversational nature of X results in over 80% of the platform's advertisers' inbound customer service requests arriving via the platform [31,32]. Unlike Facebook (developed by Meta Platforms, Inc) and Instagram (developed by Meta Platforms, Inc), which focus on connecting friends and sharing photos, X emphasizes text-based posts [33]. Given its functionality and comprehensive data archive, X was chosen as the data source for this study.

Natural language processing (NLP) has become an increasingly important set of methods in health research for extracting meaningful insights from unstructured text, supporting both clinical and patient-facing applications. NLP techniques have been applied across health care to analyze clinical notes, extract structured information from narrative records, and support decision-making processes, highlighting the role of text analytics in structuring and interpreting large volumes of health-related data [34]. In addition to clinical contexts, NLP has been used to analyze real-world patient and consumer language, including extracting health insights and patterns from free-text patient feedback and social media, demonstrating its utility in capturing perceptions, attitudes, and experiences related to health services and outcomes [35,36]. Recent work has shown how topic modeling, sentiment analysis, and related language processing techniques can complement traditional qualitative analyses by summarizing themes and sentiment patterns across large text datasets [35]. These applications provide context for this study's use of NLP methods to analyze user-generated commentary on mental health apps.

Machine-assisted topic analysis (MATA) combines machine learning techniques with human-led qualitative analysis to enable systematic exploration of large-scale textual datasets. In this approach, free-text data are first structured using structural topic modeling (STM), making them analytically tractable while preserving the richness of user-generated content. MATA keeps human judgment central to topic labeling, thematic synthesis, and theoretical interpretation, rather than relying solely on automated classification. Building on established MATA applications in health research [37,38], this study extends the framework to the analysis of user experiences of commercial mental health apps expressed on social media. Methodologically, this implementation demonstrates how MATA can surface and organize diverse user concerns at scale—spanning technical usability, content and operational challenges, commercial practices, and self-monitoring experiences—that would be difficult to capture through traditional thematic analysis alone due to dataset size, or through sentiment analysis alone due to its limited contextual sensitivity.

XSL•FO
RenderX

In this study, STM was used to organize user feedback on mental health apps by identifying patterns of word co-occurrence while incorporating relevant metadata. Human-led thematic analysis was subsequently applied to interpret and cluster the resulting topics [37,39-44].

Focusing on user experiences rather than researcher-led evaluations, this study targeted the 5 high-grossing mental health apps in December 2022: Calm, Headspace, BetterSleep, Sleep Cycle, and Waking Up [9]. These apps were selected due to their widespread use, financial success, and potential to generate relevant, representative data. When searching for mental health apps, health or meditation app criteria were applied, while fitness, weight control, and sports apps were excluded. Table 1 briefly summarizes the 5 apps and their individual global revenue totals for December 2022.

Table . The top 5 grossing mental health apps in December 2022, their monthly revenue, and brief summaries.

App name	Approximate gross global revenue in the month of December 2022	Focus of app
Calm	6,400,000	Mindfulness, relaxation, and sleep
Headspace	4,900,000	Mindfulness, meditation, and sleep
Sleep Cycle	1,400,000	Sleep tracking and gentle wake-up alarm clock
BetterSleep	1,300,000	Sleep tracking, education, and relaxation content
Waking Up	952,000	Meditation, mindfulness, and educational content
Total	14,952,000	—

The above table shows the top 5 grossing mental health apps in December 2022, their monthly revenue, and brief summaries of each app [9,45-49].

The aim of this study was to identify issues users experience when using commercial mental health apps by analyzing a large volume of user-generated content from X. Specific objectives were: (1) to use MATA to analyze user feedback and (2) to provide insights on the potential negative impacts of highly popular commercial mental health apps.

Methods

Study Design

MATA combines topic modeling with human qualitative analysis [37,42-44]. In this study, MATA was used to analyze X posts, identifying topics and generating representative quotes. Qualitative researchers then interpreted the outputs to synthesize the findings.

Data

X posts referencing the 5 highest-grossing health apps were collected using X's official API, accessed via an academic license and implemented using version 0.3.1 of the R package "*academictwitteR*" [50] (refer to Table 1). The search strategy involved using keywords combining each app's name with terms such as "app," "application," and "tracker," where relevant. Additionally, X posts mentioning the official app accounts' X handles were included in the search. A document showing the coding and keywords used is available in Multimedia Appendix 1. The date range for relevant posts gathered was set for X's inception (March 21, 2006) to the end of 2022.

The number of posts related to each mental health app gathered using R from the initial dataset is shown in Table 2.

Table . Number of posts related to each individual app gathered using R from the initial dataset after negative sentiment filtering.

App	Number of X posts contributed to dataset
Calm	574
Headspace	9984
Sleep Cycle	5527
BetterSleep	912
Waking Up	2606
Total	19,603

Preprocessing of the Data

Initially, 79,703 posts relating to the apps were gathered. The dataset then underwent negative sentiment lexicon filtering to identify posts expressing predominantly negative sentiment, consistent with the study's focus on user-reported issues and concerns relating to mental health apps. Sentiment filtering was performed using the Bing lexicon implemented through version 0.3.1 of the *tidytext* package [50]. The Bing lexicon is a curated list of words annotated with positive or negative polarity. Each post was tokenized into individual words, which were then matched against the lexicon. Matched words were assigned a sentiment score of +1 (positive) or −1 (negative), whereas unrecognized words were excluded from scoring. These values were summed within each post to produce a net sentiment score, where negative values indicated an overall negative tone. Posts with a negative net sentiment score were retained for subsequent STM and qualitative thematic analysis. After negative sentiment

XSL•FO
RenderX

filtering, 19,603 posts remained, and STM was applied to this dataset. Although this approach focused the analysis on expressions of negative user experience, some neutral or positive content remained within the final dataset, reflecting the inherent limitations of lexicon-based sentiment classification.

During additional data cleaning, app names were removed before STM was applied to organize the X posts into topics. Removing app names was crucial to prevent the STM from organizing X posts by name instead of the issues they presented. App names were reintroduced to the comments after STM had been completed. The data were preprocessed by first removing punctuation, symbols, and numbers, and then converting the text into individual token units. Common stop words were excluded, and stemming was applied to reduce words to their root forms, facilitating more efficient processing and analysis. In this study, no structured variables were included as covariates in the STM.

Structural Topic Model

Before running the models, diagnostic plots were generated to determine the optimal number of topics, considering both the relevant metrics and the goals of this analysis, while focusing on balancing semantic coherence and exclusivity [37]. An unsupervised topic modeling approach was evaluated by human coders, testing models with differing numbers of topics (5-40) and differing covariates in terms of coherence, residuals, and interpretability. A structural topic model with 10 topics and 20 posts per topic was identified as the most suitable for gaining insights based on the diagnostic statistics. Ultimately, a model without covariates was chosen.

We tested multiple candidate models across a range of topic numbers and evaluated their quality using established STM diagnostics, consistent with the approach in Sheen et al [38]. Specifically, we examined semantic coherence (how strongly words in a topic co-occur) and topic exclusivity (how distinct words are across topics) to assess each model's interpretability and distinctiveness. In addition to these quantitative diagnostics, candidate models were qualitatively reviewed by inspecting representative posts to determine whether the topics were meaningful and clearly interpretable. Based on this combined evaluation, a 10-topic model was selected because it provided the best balance: the topics were sufficiently distinct from one another (high exclusivity), internally coherent (high semantic coherence), and interpretable in terms of the substantive themes present in user comments on mental health apps. This approach mirrors the methodology used by Sheen et al [38], where the final number of topics was chosen based on both statistical diagnostics and qualitative interpretability rather than on a purely numeric criterion.

Output

Each of the 10 topics included as part of the output analysis was represented by the 20 X posts identified as the most semantically related to a given topic. The intention of the STM approach used in this study was that the posts within each topic would share commonalities because of the word co-occurrence of X posts within the generated topics, with the human researchers subsequently being able to label each topic by describing the main user issue evidenced by each topic. All 10 topics and quotes are provided in Multimedia Appendix 2.

Qualitative Analysis Process

After establishing the structural topic model, manual thematic analysis was performed by two researchers—Jack Bolter (JB) and an additional researcher—to provide interpretation of the topics. The researchers independently described each quote and labeled the STM-created topics based on the main issue raised by each topic. After independent analysis, the researchers discussed and agreed upon topic labels. A third researcher (PB) reviewed the analysis to increase the quality of the analysis. Where appropriate, the researchers organized the topics into major themes. Representative quotes for each topic are discussed in the Results section.

The following sequential steps describe how the researchers conducted the analysis following receipt of the STM output:

- Step 1: the researchers familiarized themselves with the data through repeated readings of the machine-generated topics and noted descriptions of each X-post.
- Step 2: the researchers independently added labels to describe each of the machine-generated topics.
- Step 3: the researchers discussed and reached consensus on major themes in their analyses, considering similarities and differences.
- Step 4: the researchers' findings and interpretations were documented in the Results and Discussion sections.

This study used MATA, a mixed methods approach that combines computational text analysis with qualitative interpretation to identify patterns in large text datasets. Following Bondaronek et al [37], MATA involves the application of automated topic modeling techniques to structure a large corpus of textual data into algorithmically derived topic groupings. These outputs are then reviewed and interpreted by researchers, who iteratively generate topic labels and develop higher-order themes. Rather than replacing human interpretation, the computational component is used to facilitate systematic exploration of large datasets, while interpretive analysis remains central to theme development and meaning-making.

While no automated bot or spam detection filters were applied during data collection, several aspects of the analytic process acted as a form of natural mitigation against the influence of such noise. Posts relating to the selected mental health apps were first organized using STM, which groups content based on patterns of semantic similarity. Given that bot or spam posts are often repetitive, promotional, or thematically inconsistent, such content is less likely to cohere meaningfully into stable topics.

No software was used to conduct the subsequent manual thematic analysis. Two researchers (JB and an additional researcher) independently reviewed the STM-generated topics and developed initial topic labels through close reading and interpretation of the data. An inductive approach was used for thematic labeling, with topic labels and themes generated directly from researcher interpretation of the STM outputs. The labels generated for each topic were based on the overall consistency and substantive meaning of the posts within a topic.

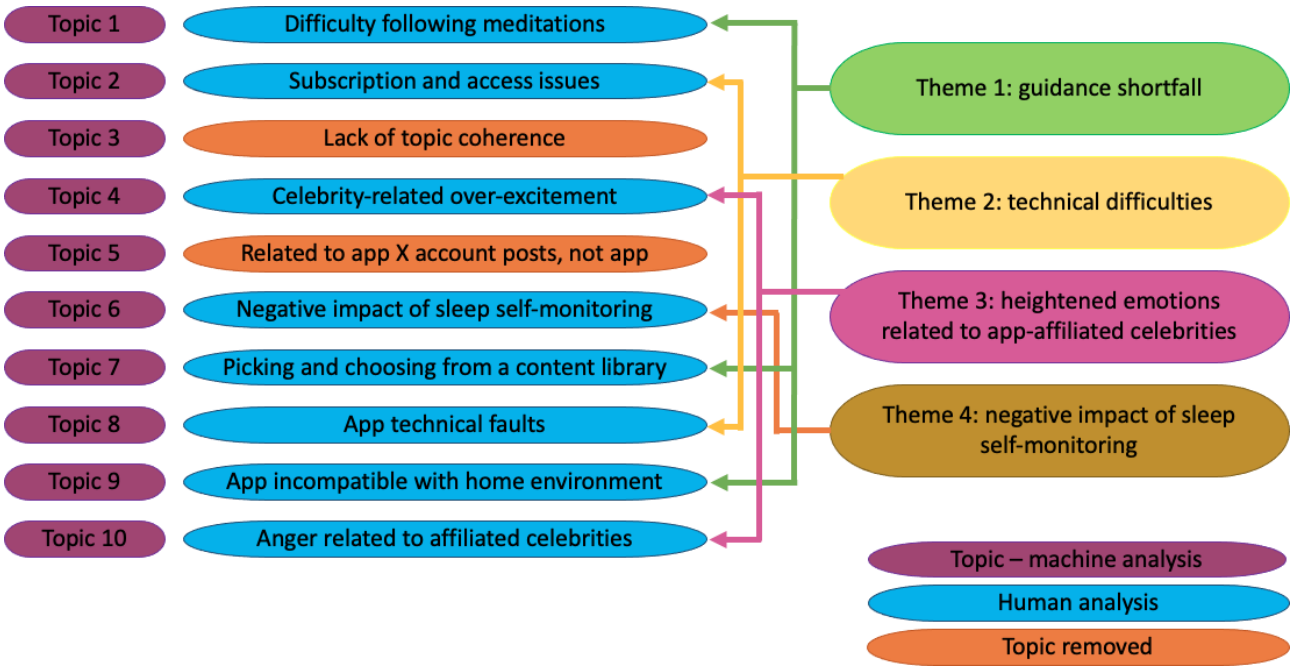
XSL•FO
RenderX

These independently generated labels were then compared and discussed. Any minor differences in interpretation were resolved through discussion and consensus. The researchers' interpretations were closely aligned, and discussion primarily served to refine and harmonize topic labels and overarching themes based on shared review of the STM outputs. Topic interpretation was therefore driven by recurring, coherent user experiences rather than individual posts. One topic was excluded entirely due to low coherence, illustrating how the human interpretive stage helped identify and remove clusters lacking a clear thematic thread, which may include random or spam-like content. In addition, not all posts within a topic contributed equally to theme definition; more detailed and thematically consistent posts were prioritized during interpretation, reducing the influence of isolated or anomalous content. While it remains possible that some bot or spam posts were present, industry estimates suggest such content accounted for approximately 10% of posts on X during the study period [51], indicating that any residual noise likely constituted a small minority and did not drive the overarching thematic findings.

Ethical Considerations

The permission to conduct the study was granted by The University of Westminster's Ethics Committee under application ID ETH2223-2307 (class 1). Users consent to X redistributing their public comments on its platform upon signing up to the platform [28]. To protect privacy, identifying details such as names and X handles were removed from reported results.

Beyond ethics approval and platform terms of service compliance, measures were taken to minimize potential harm associated with sensitive mental health-related content, including anonymization of usernames and handles. Results were primarily reported at the level of topics and themes, with a limited number of anonymized posts included as illustrative examples to support interpretation.



Results

Overview

Following data cleaning and negative sentiment filtering, 19,603 app-related X posts remained for STM topic organization (79,703 posts were gathered relating to the apps prior to negative sentiment filtering). Eight of the 10 subsequently STM-generated topics were included in the analysis, as these topics were coherent and provided insights relating to the issues experienced by users of the apps. The remaining 2 topics organized by the model were excluded from the analysis, 1 due to incoherence and the other due to comments being related to social media content rather than the apps themselves. As per Bondaronek et al [37], the researchers coded the X posts and assigned a label to each topic which summarized the main user issue identified. Eight of these topics were then organized into 4 themes (1 theme comprised a single stand-alone topic).

Figure 1 shows each of the topic labels and themes that the researchers produced to organize and derive meaning from the STM-generated topics.

Figure 1. Overview of the themes and topic labels derived from the structural topic model and interpreted through human thematic analysis by JB and an additional researcher. The guidance shortfall theme captures users' difficulties engaging with audio-guided content, including challenges understanding meditation instructions, selective and repetitive content use, and incompatibility with busy home environments. Technical difficulties reflect frustrations related to subscription access, in-app functionality, and limited responsiveness from app support services. Heightened emotions related to app-affiliated celebrities represent both positive excitement and negative reactions to celebrity involvement in app content and promotion. The negative impact of sleep self-monitoring theme highlights users' reliance on app-based sleep tracking, including benefits for some users alongside indications of reduced sleep self-efficacy and increased anxiety linked to monitoring practices.

XSL•FO
RenderX

Guidance Shortfall

The "guidance shortfall" main theme clustered 3 topics in which user comments demonstrated that additional guidance beyond the content within the apps would have helped users with their mindfulness and sleep hygiene practices.

Topic 1 focuses on users' difficulty following the apps' audio-guided meditations. Some quotes indicated trouble interpreting metaphors and concepts in the guided exercises, which appeared to hinder practice comprehension, while others demonstrated that users were physically uncomfortable while following the exercises.

> *I'm struggling with the idea of awareness in space and then being aware from it. I try to imagine it but all my awareness comes from my brain. I can imagine my awareness intermingling with space but in reality my awareness is only acknowledging space as aware from my brain.* [Topic 1, 18]

Topic 7 illustrates how users take the opportunity to pick and choose content from these apps and may use the same pieces of content repeatedly as opposed to following a structured course. Comments often appeared to be in response to posts from the apps' social media accounts asking X users what their favorite pieces of content on their respective apps were. For example, the following comment highlights one user's preference for two sleep podcasts on one of the apps:

> *Moon Buggy or Rainy Day Antiques... for the ZZZZs....* [Topic 7, 10]

Topic 9 was characterized by users commenting that they found their busy home environments to be incompatible with the apps. For example, one user reported difficulty following the relaxation and meditation guidance of the apps while they were aware of other noises within their home.

> *Tonight's episode was accompanied by the sounds of the hamster trying to break out of his cage, 6yr old's toy tiger roaring & 3yr old having coughing fit.* [Topic 9, 20]

Topic 9 also illustrated how busy home environments can interfere with recordings used to provide sleep quality analysis.

> *My [app name] app is supposed to record me snoring but most of the recordings are of (R)ingo snoring or him hissing at (B)owie.* [Topic 9, 5]

Technical Difficulties

The "technical difficulties" theme comprised 2 topics describing how users experienced technical problems when trying to access the apps and while using the apps.

Topic 2 was focused on subscription and access issues. Many users showed frustration due to not having gained the access levels they are entitled to despite having paid their subscription or being due access for another reason (eg, promotions allowing app access to individuals in certain professions).

> *… I'm confused. I paid £49.99 annual subscription but I still have some areas locked. Why is this please(?).* [Topic 2, 2]

Such frustration was exacerbated when users struggled to contact app staff to seek support or compensation.

> *(I have) been trying to contact you for several days by email. No response from your team. Very disappointed. My subscription fee charged was a lot higher than what was shown in−app. Please reverse this immediately...* [Topic 2, 16]

Topic 8 highlighted that some users experienced negative emotions due to technical faults encountered while using the apps.

> *I'm confounded by how LOUD the default volume is on music, SFX, stories, etc ... with no apparent way to adjust the volume, in app. If the answer=turn down iPhone volume, then alarm volume is compromised. Unusable. Am I missing something?* [Topic 8, 18]

As with topic 2, such frustration was exacerbated when users struggled to contact app support staff:

> *How do I escalate a fault on my app which I raised on 5 Aug(?) (It is) with the engineers but "Sadly, we don't currently have an estimate for when the issue might be fully resolved(.)"* [Topic 8, 20]

Heightened Emotions Related to App-Affiliated Celebrities

The main theme related to "app-affiliated celebrities" clustered 2 topics showing how users experienced heightened emotions—both positive and negative—about public figures with links to the apps. Such affiliations were generally due to celebrities either creating content for the apps or having sponsorship deals for the apps on their own platforms.

Topic 4 demonstrated that celebrity partnerships with the apps can have an effect of elevating users to states of excitement that are counter to the states of calm and relaxation on which the apps are marketed. Several X posts were all in capital letters and related to an appearance of a famous popstar on one of the apps to narrate content.

> *OMFG, I'm dead. The shoes not even on his feet. His hat the beard his outfit. OMG.* [Topic 4, 19]

While comments in topic 4 were largely positive, if perhaps excitable in tone, those in topic 10 often expressed anger in relation to celebrities affiliated with the apps.

> *(Celebrity name) (is) a fraud owned by China… the most overrated player in NBA history.* [Topic 10, 3]

Negative Impact of Sleep Self-Monitoring

Topic 6 is a stand-alone theme relating to the reliance some users seemed to have on using these apps to aid their sleep and the sleep self-monitoring they performed via the app. Many of the user comments were positive about how the apps impacted their sleep.

> *The (app name) App for iOS is a game changer. Wakes you up at the end of a cycle so as to not startle you awake from REM sleep.* [Topic 6, 3]

XSL•FO
RenderX

However, other posts hinted that users' focus on app statistics might negatively impact their sleep self-efficacy and be problematic due to excessive sleep self-monitoring.

> *Ok party people, I'm totally addicted and fascinated by the (app name) app! Always knew I sucked at sleeping but WOW my graphs r shocking!* [Topic 6, 14]

Discussion

Principal Findings

This study investigated issues users experience with mental health apps by analyzing 19,603 negative sentiment X posts related to the 5 highest-grossing mental health apps (79,703 posts relating to the apps were gathered prior to negative sentiment filtering). Using machine learning with qualitative analysis, the data were organized into 10 topics and interpreted by researchers into four main themes: guidance shortfalls, technical difficulties, heightened emotions linked to app-affiliated celebrities, and the negative impact of sleep self-monitoring. These themes encapsulated a range of richly detailed user concerns, including frustration with insufficient in-app guidance, technical obstacles, overexcitement and distress related to celebrity presence, and a potentially detrimental overemphasis on sleep data. Although users did not report direct feelings of unsafety, the absence of in-person support and the intensity of negative emotions expressed suggest that some users perceived limitations in the ability of unregulated mental health apps to meet their support needs.

Several findings from the study align with existing research. Users' difficulties with guided meditation and feelings of being unsupported resonate with Crane et al [52], who emphasize the importance of instructor feedback in mindfulness practice via the interactive inquiry section of classes, and Ruse et al [53], who report dissatisfaction stemming from the lack of human interaction in mental health apps. Users' perceptions of feeling unsupported by audio guidance during guided meditations can be interpreted through self-determination theory, which posits that sustained motivation depends on supporting basic psychological needs such as autonomy and competence; when digital guidance fails to scaffold these needs, users are less likely to internalize the practice and maintain engagement. Self-determination theory has been applied in human-computer interaction research to explain how technology design can either foster or undermine intrinsic motivation by shaping whether users feel capable, self-directed, and meaningfully engaged [54]. While audio guidance is intended to support practice, limited personalization and adaptive feedback—which are more feasible in in-person meditation classes and groups—may diminish users' sense of autonomy and competence, reducing the subjective feeling of being supported. Similarly, the observation that technical issues led to frustration and stress supports findings by Haggag et al [55] and Woods et al [56], who highlight usability problems as key barriers to engagement and therapeutic benefit. The study's insights into the risks of sleep self-monitoring—such as anxiety over sleep statistics and potential overfocus on tracking—also reflect earlier research by Baron et al [57] on orthosomnia (the idea that preoccupation with sleep quality and tracking results may paradoxically impair sleep quality).

Recent research has critically examined the user experience and interpretive practices associated with sleep tracking technologies, highlighting issues of data literacy, accuracy of app data, and optimization logic assumptions. O'Neill and Nansen [58] analyzed how mobile sleep apps do not simply monitor sleep but actively intervene in users' sleep-wake rhythms through features such as "smart wake-up" alarms and brainwave entrainment sounds. They show how these functions are underpinned by optimization logics that position sleep as something that can be measured, managed, and improved through algorithmic systems, thereby shaping how users understand and act upon their own sleep. The authors illustrate that this is problematic given the potential for these apps to produce inaccurate user sleep data. Similarly, Liang et al [59] demonstrate that users often grapple with interpreting sleep data, questioning its reliability and struggling to translate metrics into meaningful or actionable insights. Together, this literature underscores that engagement with sleep tracking apps involves complex processes of interpretation, negotiation, and trust. However, it also demonstrates that such trust can also generate user anxiety that they are not achieving optimal sleep.

In terms of novel contributions, this study found that users expressed strong emotional responses to celebrity content within mental health apps, which some posts suggested could detract from experiences of calm, focus, and emotional regulation that users associated with mindfulness practices. Existing research related to celebrity affiliations with mHealth apps has largely focused on the commercial benefits rather than their potential to interfere with therapeutic outcomes [60]. This study also highlights how apps' associations—or disassociations—with public figures can provoke strong emotional responses in users, including anger, particularly when these public figures are involved in polarizing discourse. This suggests that app branding and celebrity affiliations may be associated with socially and politically charged reactions among users. While prior work has explored the marketing benefits of celebrity endorsement, the psychological and affective implications for users remain underexplored in the mHealth app literature. The findings relating to celebrity affiliations for commercial purposes contribute to a growing body of literature that critiques the ways in which digital wellness and mindfulness apps draw from traditional Eastern philosophies—such as Buddhist practices rooted in ethical precepts such as sila—while stripping away their moral and communal dimensions [61-63]. These practices follow other recent examples of traditional mindfulness practices being reframed within Western commercial frameworks to promote individual calm, emotional regulation, or productivity, raising questions about cultural appropriation and the commodification of spirituality.

It was also found that some users repeatedly engage with familiar or favorite content. Such repeated use of the same content as opposed to following a structured program may mean users are less likely to experience meaningful behavior change. While Bol et al [64] found that autonomy and customization when using mHealth apps can increase behavioral intentions for users with a high need for autonomy, their study also

XSL•FO
RenderX

reported that, on average, customization did not lead to greater perceived control, motivation, or intention to act. While user autonomy may facilitate short-term engagement, long-term behavioral change may require more structured, theory-driven approaches, such as those informed by the Health Action Process Approach [65]. Further research is warranted to clarify the conditions under which user autonomy supports or hinders behavioral outcomes in mHealth app contexts.

Strengths and Weaknesses

A significant strength of the study lies in its methodological approach, using STM in combination with qualitative analysis to effectively synthesize insights from a vast volume of real-world data. This approach, as demonstrated by Bondaronek et al [37], proved reliable and valid. The use of X posts enhanced ecological validity by capturing unfiltered user experiences in situ [26].

A key limitation of this study lies in the lack of nuance inherent in the methodological approach used. While STM is effective for identifying broad thematic patterns across large datasets, it is not well suited to capturing the complexity and depth of individual user experiences. This is compounded by the low character limits of most X posts within the available data, which constrain user expression and may exclude more detailed or reflective insights. Moreover, the diversity of the apps analyzed—ranging from mindfulness-focused to sleep-oriented platforms—introduces variability that may limit the generalizability of specific findings across the broader category of mHealth apps. Future research could address these limitations through follow-up interviews or focus groups to help verify the findings and gain a richer understanding of the identified user experiences.

The absence of automated spam or bot detection represents a limitation of this study, as no specific bot-detection procedures were applied to the dataset prior to analysis. Consequently, the STM input data included a degree of automated or low-quality content, introducing noise into topic summarization and contributing to some less coherent or contextually relevant posts within topics. Although spam and bot detection methods may have reduced this noise and potentially improved topic coherence and interpretability, such approaches are imperfect, particularly when applied to large-scale social media datasets, meaning that some automated content may still have remained even if filtering had been undertaken. To minimize the influence of noisy data on interpretation, the analysis focused on topics that demonstrated coherence and relevance to user experiences, with an incoherent topic and another unrelated to user experiences being excluded from the subsequent analysis.

Another key limitation of this study is that it draws on publicly shared social media posts, and we cannot infer that users' experiences reported online correspond to clinically assessed mental health outcomes. The themes identified reflect users' self-reported issues when using mental health apps, rather than verified experiences of anxiety or other clinical conditions. Consequently, the findings should be interpreted as indicative of the types of issues users report, rather than evidence of therapeutic effectiveness or harm.

It is also important to recognize that X users are not fully representative of the broader population of mental health app users, which may limit the generalizability of our findings. Demographically, X's user base skews toward younger adults, with an estimated 71.6% of users being <34 years in 2025. The X user base is also male-dominated, with males comprising 63.7% of the global users in 2025 [66]. Furthermore, for the time period from which the data were gathered (2006 up until the end of 2022), X users tended to be more highly educated and comparatively affluent than the general population, with higher proportions of adults in higher income brackets and tertiary education levels [67]. These demographic profiles suggest that perspectives captured in our analysis may overrepresent the experiences of younger, more educated, and higher-income individuals, while underrepresenting older adults, lower-income groups, and those who do not engage with X as a forum for discussing app experiences.

Character limits were only increased to 4000 characters for paying subscribers after this study's data were collected, meaning that X posts in this study had character limits of 140 (for X posts posted prior to November 6, 2017) and 280 (for X posts posted from November 7, 2017, onward) [68]. Such brevity was advantageous for the manageability of the dataset, but it also limited the extent to which users were able to articulate their experiences.

The dataset was unevenly distributed across the 5 included mental health apps, with some apps generating substantially more posts than others. This variation reflects differences in app popularity and user engagement on the platform, rather than a sampling bias introduced by the study design. However, this imbalance may have influenced the relative prominence of topics identified through STM, as apps with higher volumes of user-generated content are potentially more likely to contribute greater proportions of text to the corpus. The study was designed to identify common issues associated with mental health app use more broadly, rather than to conduct app-specific comparisons, and therefore findings should be interpreted at this aggregate level. No sensitivity analyses were conducted to rebalance the dataset or isolate app-specific effects, as this was beyond the scope of the study's exploratory aims.

Implications for Research, Practice, and Policy

App developers should address the lack of guidance support identified in user reports by strengthening onboarding processes, in-app guidance, and wayfinding features. Difficulties navigating app content and uncertainty about how to engage with interventions suggest a need for clearer instructional scaffolding and more explicit signposting of core features. To ensure such guidance supports meaningful behavior change rather than surface-level engagement, interventions should be aligned with established behavior change theories such as the Health Action Process Approach [65].

User complaints relating to subscription practices and billing indicate a need for greater transparency around pricing structures, trial periods, and cancellation processes, as well as more responsive customer support mechanisms. Similarly, reports of technical instability and disrupted functionality point to the importance of improving app reliability to prevent

XSL•FO
RenderX

frustration and disengagement. Together, these issues suggest that usability and commercial design decisions may contribute to users reporting frustration, stress, and feelings of being unsupported, potentially diminishing the perceived value of mental health apps.

The findings of this study suggest that greater consideration should be given to the regulation and oversight of mental health apps. Policymakers should consider frameworks to evaluate and certify digital mental health tools, especially those that might be used in place of traditional therapeutic support. Certification schemes could distinguish evidence-based digital therapeutics from general wellness apps. Dialogue between public health bodies and app providers, as well as public information campaigns, may help users make more informed choices about mental health support and whether they should use mental health apps. Clinicians could also use the present findings to support patients in critically evaluating app-based mental health tools and, where appropriate, integrate curated lists of validated apps into care strategies to complement—not replace—traditional therapeutic support.

Future research should test the robustness of this study's STM-based findings across diverse populations and mental health contexts. Additional studies could explore whether key user issues were missed due to the analytical approach of STM. Research is needed to evaluate the psychological outcomes associated with mental health app use and to explore users' perceptions regarding the role of these apps alongside, or potentially in place of, professional support.

Conclusion

This study provides further evidence that STM can be combined with human qualitative methods to quickly analyze large volumes of X data. With data relating to the 5 most popular mental health apps analyzed via this approach, the researchers were able to expeditiously identify several issues encountered by users. This method, therefore, has the potential to be used to swiftly provide insights relating to how individuals experience various digital health interventions.

Acknowledgments

Thanks are extended to Maria Ceka, one of my fellow students in the MSc Health Psychology program at the University of Westminster, for independently performing thematic analysis of the data before collaborating with me to reach consensus on the data's topic labels and themes. Jack Bolter is a graduate of the MSc Health Psychology program at the University of Westminster. No generative AI tools were used in the preparation of this manuscript.

Funding

PB is supported by the Wellcome Trust (Project No. 300252/Z/23/Z).

Data Availability

Outputs generated by the structural topic model are available in the Multimedia Appendices. The authors are available to provide further methodological details regarding data collection and data preprocessing upon request.

Authors' Contributions

JB conducted the formal analysis and wrote the original draft of the paper, as well as reviewed and edited subsequent versions. TP was responsible for data curation and software. PB contributed to the conceptualization, methodology, supervision, and validation of the study.

Conflicts of Interest

None declared.

Abstract

Background: Adolescents living with HIV often experience poor antiretroviral therapy (ART) outcomes due to multiple barriers affecting medication adherence. Effective self-care interventions are needed to address these challenges. Mobile phones are widely used by the adolescent population and therefore present an opportunity to enhance ART adherence using mobile phone–based interventions. However, research on mobile phone access among adolescents living with HIV, usage patterns, and perceptions of mobile phone–based interventions is limited in Eswatini.

Objective: This study aimed to explore these aspects to inform effective mobile health strategies for enhancing ART adherence among adolescents living with HIV.

Methods: We conducted a qualitative study using in-depth interviews in December 2023. A total of 29 adolescents living with HIV aged 10 to 19 years and enrolled on ART were purposively sampled and interviewed from 5 Teen Clubs in the Hhohho region of Eswatini. Interviews were audio-recorded and transcribed verbatim. Topic areas covered were mobile phone accessibility, usage patterns, and perceptions on the use of mobile phones to facilitate ART adherence. The data were analyzed using the deductive-inductive coding approach.

Results: Of the 29 participants, 15 (52%) were female, and 19 (65.5%) were aged between 15 and 19 years. The study findings indicated high mobile phone access among participants, with primary usage focused on making and receiving calls, as well as engaging with social media. Three themes emerged regarding the use of gamified interventions to support ART adherence. First, the use of gamified interventions aimed at ART adherence among adolescents living with HIV was deemed feasible based on mobile phone access and past experiences with mobile games. Second, 3 main qualities of successful gamified interventions were identified as being supportive, being educational, and ensuring secure and confidential connections with other players. Finally, confidentiality and mobile phone access factors were highlighted as potential concerns when designing gamified ART adherence interventions.

Conclusions: The findings suggest potentially high access and usage of mobile phones among adolescents living with HIV on ART in Eswatini. This provides an opportunity to leverage mobile technology to enhance ART adherence through gamified interventions. However, it is essential to carefully consider the specific needs and concerns of adolescents living with HIV in the design of these interventions to ensure their successful uptake and sustainability.

KEYWORDS

adolescents living with HIV; antiretroviral therapy; ART adherence; mobile phones; mobile health; gamified interventions; Eswatini

Introduction

Eswatini's adolescents have consistently shown lower antiretroviral therapy (ART) outcomes, such as viral load suppression (VLS), compared to the adult population. In 2023, Eswatini recorded a 96% VLS rate among adults, while adolescents aged 15 to 19 years reported a 77.8% viral suppression rate among those on ART [1,2]. Although there

XSL•FO
RenderX

has been a very slight improvement compared to 2017 data where VLS was 76% among adolescents and young people, it remains below the Joint United Nations Programme on HIV/AIDS (UNAIDS) 90% VLS target for 2020 [3,4]. Low VLS is associated with poor ART adherence, leading to opportunistic infections and subsequently AIDS-related deaths [5-7].

Nonetheless, Eswatini has made tremendous progress in combating the HIV epidemic, despite having the highest prevalence of HIV globally at 24.8% [1]. This progress has positioned the country among the first to meet the 2030 UNAIDS targets ahead of the set date [1,2]. The UNAIDS targets aim for 95% of people living with HIV to know their status, 95% of those diagnosed to be on ART, and 95% of those on ART to achieve viral suppression by 2030 [8]. Eswatini has achieved these targets through successfully implemented interventions promoting ART adherence [2]. For instance, in 2017, the country adopted the universal test and treat guidelines and coupled them with interventions promoting ART adherence counseling, resulting in the implementation of a differential model of ART care [9].

However, globally, interventions aimed at improving ART adherence have proven to be more effective in the adult population, while adolescents remain behind [10]. A systematic review conducted in 2015 highlighted that few interventions have been implemented among younger population groups globally [10]. This discrepancy is particularly pronounced in sub-Saharan Africa (SSA), which is home to 70% of the global population living with HIV and where adolescents account for 90% of the global adolescents living with HIV [8,11]. ART outcomes are also poor among the adolescent age group, resulting in 65% ART adherence and 55% VLS among adolescents in the region [12]. Despite these challenges, interventions targeting ART adherence among adolescents living with HIV are limited compared to those available for adults [13,14]. Only a few interventions, such as HIV counseling, community and facility-based support, and family-based economic empowerment programs, have been reported in previously conducted studies [10,15-17].

The potential of digital technology, particularly mobile health (mHealth), in supporting ART adherence among adolescents living with HIV remains largely underexplored, as most studies continue to combine adolescents with young adults [18,19]. For example, a systematic review of mHealth interventions targeting adolescents and young adults identified 8 studies focused on ART adherence in this population [19]. Of these, only 1 study exclusively targeted adolescents; the rest grouped adolescents with young adults, and 1 study even included children [19]. Furthermore, studies have been conducted in only 5 countries within SSA (Nigeria, Kenya, Uganda, South Africa, and Zimbabwe), highlighting the still limited implementation and evaluation of mHealth-based interventions in other high-burden settings such as Eswatini, which has the highest HIV prevalence globally [14,19]. Despite this limited focus, evidence from other African countries indicates that mHealth interventions can significantly improve adherence rates and VLS among young populations [19,20]. The positive influence of mobile phone–based interventions has been bolstered by the widespread accessibility and usage of phones among young people. As of 2024, an estimated 5.4 billion individuals owned mobile phones globally, with a total of 9.1 billion mobile phone subscriptions registered worldwide [21]. On the African continent, approximately 577 million people owned mobile phones, accounting for 1.1 billion mobile subscriptions [21]. Regarding internet access, 5.5 billion people (68% of the global population) were internet users in 2024, including 456 million individuals in Africa [21]. Notably, young people represent the most connected demographic, with 78.5% of global internet users aged between 15 and 24 years. In Africa, young people constituted 53% of internet users [21]. In 2022, Eswatini, a country with 1.3 million people, reported 1.5 million phone subscriptions [22]. Although specific data on phone ownership among adolescents are scant, a systematic review showed that young people and adolescents spend a significant amount of time on their phones, leading to phone addictions [23]. Adolescents have been reported to be particularly addicted to social media and gaming [24,25]. Studies have also reported the positive effect of mobile games in promoting medication adherence [26]. However, there is a need for tailored interventions where the end user actively participates in the design of these interventions [27].

Therefore, access to phones can be leveraged in settings such as Eswatini, where adolescents have poor ART outcomes compared to the adult population. However, there are limited data on phone ownership, accessibility, and usage among adolescents in the country. Additionally, studies have shown the importance of end-user participation in the design of health behavior interventions. We explored mobile phone access, usage patterns, and perceptions of adolescents living with HIV regarding the use of gamified interventions aimed to improve ART adherence in Eswatini.

Methods

Study Design

This was a qualitative study conducted in December 2023 using in-depth interviews (IDIs) with 29 adolescents living with HIV in Eswatini. This approach provided valuable insights from adolescents living with HIV, who have a unique understanding of the types of interventions that may be most effective for them [28].

Study Setting

The study was conducted among adolescents living with HIV accessing ART care through Teen Clubs in the Hhohho region in Eswatini. The Hhohho region is located in the northwestern part of the country and houses the capital city, accounting for 30% of the total population [29]. This region is considered the most economically advanced in Eswatini, as it has the most urbanized population and is home to the headquarters of many corporations, as well as being dominated by the forestry industry, which is among the most important sectors of the country's economy [29]. The region comprises both urban and rural settings and has 71 health facilities, including private, public, military, faith-based, and not-for-profit hospitals, health centers, public health units, and clinics [30]. These health facilities play a critical role in HIV prevention and management

XSL•FO
RenderX

through services offered from the community level to the tertiary level (hospitals). These services include the differentiated models of ART care, such as Teen Clubs [9].

Teen Clubs, a model of ART care for adolescents with disclosed HIV status, use lay health care workers also known as expert clients to provide support and education about ART and HIV [9,31]. Expert clients are HIV-positive adults whose primary role includes providing adherence counseling, tracking clients lost to follow-up, conducting pill counts to monitor medication adherence, and supporting adolescents in navigating psychosocial challenges such as stigma, suicidal ideation, and orphanhood [31]. They work collaboratively with nurses to help alleviate the clinical workload involved in managing adolescents living with HIV [31]. In 2023, there were 99 Teen Clubs with 2308 members in the country (Swaziland National AIDS Programme, National Facility Teen Clubs, Eswatini Ministry of Health, unpublished report, 2023). Of these, 31 Clubs with 1464 members were from the Hhohho region. With the assistance of the Ministry of Health, Swaziland National AIDS Program (SNAP), and the National Paediatrics HIV Care and Treatment department, 5 clubs from the Hhohho region that had been active for at least 2 years were conveniently chosen for data collection [28]. Within each club, at least 5 adolescents living with HIV meeting the inclusion criteria were purposively selected [32]. To ensure the representativeness of perceptions and experiences of all adolescents living with HIV in Teen Clubs, the selected participants included both male and female participants, adolescents from both age groups (10-14 years and 15-19 years), and at least 1 peer educator from each club [32]. Peer educators are also known as community adherence to treatment support (CATS) and are involved in educating and supporting their peers using door-to-door campaigns, especially for adolescents living with HIV lost to follow-up or with poor ART outcomes [33]. The inclusion criteria required adolescents aged 10 to 19 years who were aware of their HIV status and had been members of the Teen Club for at least 6 months at the time of data collection to ensure a comprehensive ART history.

Participant Recruitment Process

Expert clients assisted in the identification of potential participants and were referred to the researcher for further explanation of the study. Adolescents who were willing to be part of the study and met the inclusion criteria were given a detailed study information sheet in both siSwati and English. Adolescents aged below 18 years were given the information sheet, along with the researcher's contact information, consent, and assent forms to share with their guardians. Adolescents aged 18 years provided their voluntary consent to participate in the study. Interviews took place in December 2023 following the receipt of signed consent and assent forms. A total of 29 adolescents meeting our inclusion criteria were recruited. The sample size was guided by the principle of data saturation in conducting qualitative studies [32]. The sample size for achieving data saturation was informed by previous studies conducted among similar populations, using comparable data collection tools, specifically semistructured interview guides [34,35]. Data saturation was achieved when no new relevant information emerged from the participants [28]. Data saturation was assessed by evaluating the repetitiveness of responses. Specifically, data collection continued until no new or significant information emerged from the interviews.

Data Collection and Management

An IDI guide was developed based on an extensive literature review of studies examining barriers and facilitators of ART adherence, as well as interventions targeting ART adherence among adolescents living with HIV. The interview guide included topics on ART and ART adherence experience, mobile phone accessibility and usage patterns, barriers and facilitators to ART adherence, and perceptions of the use of mobile phones to facilitate ART adherence (Multimedia Appendix 1). To ensure the validity of the questions, the interview guide was pilot-tested through 2 interviews with adolescents living with HIV who were not included in the final sample [28]. The interview guide, along with all consent and assent supporting materials, was translated into siSwati to ensure comprehension by all participants. Consequently, the IDIs were conducted in either siSwati or English, depending on the participants' preferences, and were audio-recorded. Each interview lasted about 45 minutes, and interviews were conducted in private rooms provided by each health facility or other locations of participants' preference. To protect participants' identities and ensure confidentiality, personal identifiers, such as names, were not used during interviews.

The audio recordings were transcribed verbatim, and those in siSwati were translated into English. Personal identifiers of participants were not included in both the transcripts and audio files; instead, codes were used to identify participants to maintain confidentiality. Both the transcripts and audio recordings were securely stored on a password-protected computer.

Data Analysis

A deductive-inductive coding approach was used for data analysis [36]. The initial code frames were developed based on the research question being "Can mobile games be used to facilitate ART adherence?", while additional themes emerged inductively from the participants' responses. A code framework was developed, and transcripts were coded manually [28,32]. The code book was reviewed by 2 independent investigators (LDH and CSS) for comprehensiveness and appropriateness [37]. Differences were discussed and resolved collaboratively by the 2 investigators (LDH and CSS), and the final codebook was reviewed and validated by PSN.

Ethical Considerations

Approval to conduct the study was sought from the Stellenbosch University Health Research Ethics Committee (reference number: S24/02/037) and Eswatini Health and Human Research Review Board of the Ministry of Health (protocol reference number: EHHRRB143/2023). Furthermore, a letter of support from hospital management teams was obtained from the Ministry of Health, Department of Health Services. Finally, all participants and guardians in case of participants below the age of 18 were given detailed information on the study and provided consent and assent. Participants were informed that participation in the study was voluntary, and they were free to withdraw from the study at any point.

Results

Demographic Characteristics of Participants

A total of 29 participants (n=14 males and n=15 females) were included in the study. The majority (n=19, 65.5%) of the participants were aged 15 and above. The mean age of the participants was 16.5 (SD 1.08) years, with an average of 10.8 (SD 3.99) years on ART and 5 (SD 3.99) years of Club membership. The majority (n=23, 79%) of the participants were diagnosed with HIV from birth, while only 2 (7%) were diagnosed later in life (Table 1).

Table . Characteristics of participants.

Characteristics	Values, n (%)
Age group (y)	
10 - 14	10 (34.5)
15 - 19	19 (65.5)

[a]ART: antiretroviral therapy.

Phone Ownership and Usage

A total of 28 (96.6%) participants either owned (n=19, 65.5%) or shared (n=9, 31%) a phone with their guardian or siblings. Among those who owned or had access to a phone, 16 (57.1%) used a smartphone, while 12 (42.9%) used a feature phone (Table 2). The majority (17/19; 89.5%) of those who owned phones were older adolescents (15-19 years old), and younger adolescents (7/9; 77.8%) were most likely to share the phone with either guardian or siblings. Only older adolescents reported uncontrolled time on the phone, while younger adolescents had their phone usage controlled by guardians.

Themes on the Perceptions of Gamified Interventions Among Adolescents Living With HIV

Overview

Three themes reflecting the perceptions of adolescents living with HIV on the use of gamified interventions to improve ART adherence emerged in this study. These were (1) feasibility of gamified interventions, (2) qualities of gamified interventions, and (3) concerns about the use of gamified interventions to enhance ART adherence (Table 3). Detailed themes with the supporting codes are provided in Multimedia Appendix 2.

XSL•FO
RenderX

Table . Themes, subthemes, and codes on the use of gamified interventions to enhance antiretroviral therapy (ART) adherence among adolescents living with HIV.

Themes and subthemes	Code
Gamified interventions are feasible	
Phone access and use	• Previous game exposure • Positive game experience
Qualities of gamified interventions	
Supportive	• Reminders • Support group
Educational	• Benefits of ART • Living with HIV
Secure and confidential connection	• Dependable or trustworthy • Prevention of unintended disclosure
Potential concerns about gamified interventions	
Confidentiality	• Unintended disclosure
Phone access factors	• Phone costs • Internet bundles cost • Network availability

Gamified Intervention Feasibility

Most participants reported that the use of gamified interventions to support ART adherence among adolescents living with HIV was feasible, given their access to mobile phones and previous exposure to games. Thus, participants reported that the success of gamified interventions is not only based on mobile phone access but also on having prior experience of playing other mobile games:

> *You see auntie, we play lots of games so this can work too but then like myself I can only play it once in a while you see because I don't own the phone … but it can help.* [Female adolescent living with HIV, aged 15]

Additionally, the practicality of a gamified intervention was perceived to be influenced by the participants' experiences with games, particularly when those experiences were positive. A participant also further noted that a gamified intervention might be more appealing to younger adolescents than older adolescents:

> *I think it can work auntie especially among the young ones because those ones enjoy playing games… myself, I am not a game person but into blogs and other social media platforms because I don't find games interesting you see.* [Male adolescent living with HIV and peer educator, aged 19]

Qualities of Gamified Intervention

Overview

Participants reported that the gamified interventions should possess certain qualities for them to yield positive results in improving ART adherence among adolescents living with HIV. The qualities of a gamified intervention included being able to provide support to the players, being educational, and finally ensuring user HIV status privacy.

Supportive

First, most participants reported that a game aimed at improving ART adherence should offer support to the players, as they identified support as a key facilitator for ART adherence:

> *You see auntie, some of us will benefit from a mobile game if it provides support as it's hard to live with HIV especially where everyone else is negative … It will be like you have something you can do and like someone who understands you and when you play you are happy.* [Male adolescent living with HIV, aged 18]

A mobile game that acts as a reminder for taking their medication would be very vital, as participants indicated that they often forget to take their medication on time:

> *You see auntie, a game where like when you play you learn in the process. Like when you play you can even remember to take your pill and know why it is important.* [Female adolescent living with HIV, aged 18]

Finally, some participants revealed that a multiplayer game could provide support through networking and sharing of experiences, especially if the game can be played in real-time with others:

> *You know a game where I can be in my home and play with someone who is in Manzini, that one can work and even better if I know the person is also living with HIV and we can even chat outside the game even though we don't know each other … sometimes talking to a stranger is better auntie*

XSL•FO
RenderX

> *because they won't gossip about you.* [Male adolescent living with HIV, aged 19]
>
> *You know those racing games auntie where you have more than one player and even better if you know the players are real … those games are the best.* [Male adolescent living with HIV, aged 17]

Educational

Participants reported that a mobile game with an educational component could benefit adolescents living with HIV on ART and improve adherence. They explained that the educational benefits would include information on the advantages of ART and guidance on living with HIV. This information would be critical in teaching players the importance of ART adherence and encouraging them to persevere despite life distractions:

> *For me a game where you are fighting using a gun and when you shoot it's an indication that what happens or the results of taking your pills.* [Female adolescent living with HIV, aged 17]
>
> *[T]he game can work for us like encourage us while teaching us about the pills That's what I can say … it can be a game like avatar you see where if you fall at this point, even your life falls … yes auntie like reminds us that even if you forget your pill, don't give up like the game when they shoot you lose a life but when you keep fighting you gain more lives, something like that.* [Male adolescent living with HIV, aged 19]

Additionally, an educational game could be crucial in guiding adolescents living with HIV as they make life choices that influence their future. These choices include staying positive about life and teaching others that living with HIV does not mean a shortened lifespan; one can still live and enjoy their life:

> *I think a game that will teach people when they play about life with HIV so that they know more and the things to do to make sure one stays well.* [Female adolescent living with HIV, aged 14]
>
> *[S]ometimes you have questions about HIV in general and you have to wait for the day you go to the health facility, you see the game can be helpful if it can answer some of the questions and you can even play with other people like children so they know more about HIV because now it's like HIV means one will die … like I use poetry to teach my friends and imagine if it's a game and we play and they learn.* [Female adolescent living with HIV, aged 17]

Secure and Confidential Connection

Participants emphasized the importance of privacy and confidentiality in mobile games, especially those incorporating social connection features. While they expressed interest in multiplayer games, they strongly preferred designs that would safeguard their privacy and prevent unintended disclosure of their HIV status during gameplay. Participants indicated a preference for playing with strangers, believing this would better protect their identity. However, if the game allowed communication between players, they suggested it would be more acceptable if the other players were also living with HIV. This would create a safe space for sharing experiences without fear of stigma, gossip, or unwanted disclosure:

> *You know a game where I can be in my home and play with someone who is in Manzini, that one can work and even better if I know the person is also living with HIV and we can even chat outside the game even though we don't know each other … sometimes talking to a stranger is better auntie because they won't gossip about you.* [Male adolescent living with HIV, aged 19]

Potential Concerns About the Gamified Interventions

Overview

Participants reported concerns regarding a mobile game aimed at supporting ART adherence among adolescents living with HIV. These concerns were critical to consider in the design of the intervention to ensure its success. Participants highlighted 2 main concerns: the possibility of the intervention leading to unintended disclosure of their HIV status and factors associated with phone access and use, which include the financial implications and network access.

Unintended Disclosure

Most participants revealed that inasmuch as they believed a mobile game can assist in supporting ART adherence, there were concerns regarding unintended disclosure if the name or some of the information could be traced to HIV or people living with HIV:

> *We play games like me I normally play games from my mom's phone, and I enjoy it a lot (laughs) but then auntie what if someone sees the game and can tell that it's about HIV and now, they will be talking about my status.* [Female adolescent living with HIV, aged 17]
>
> *A game one I can play and even if someone can see but will not be able to tell it's for people living with HIV … like my cousins can also play it without them knowing it's for us.* [Female adolescent living with HIV, aged 14]

Mobile Phone Access Factors

Mobile phone access was identified by participants as a key concern in the potential success of gamified interventions. Specifically, participants raised concerns about smartphone ownership, noting that while they had access to basic or feature phones, they did not own smartphones, which are typically required to run gamified apps:

> *Mobile games can work auntie, but problem is like myself, I don't have a phone and the one I use is not a smart phone so this will not benefit some of us.* [Female adolescent living with HIV, aged 15]

Second, participants expressed concerns that even if the games could work, the cost of internet bundles would deter their success. Most adolescents do not have income and would be unable to afford the cost of internet or data bundles that would be required for online games:

XSL•FO
RenderX

> *You see auntie, some of the adolescents here cannot afford to buy internet bundles and you know some games need you to be online.* [Male adolescent living with HIV and peer educator, aged 19]

Finally, participants cited limited mobile network coverage in some of the geographical locations in the country as making it difficult to have access to a mobile phone. They believed that the lack of mobile network coverage would hinder some of them from taking part in the games:

> *I don't know auntie, but you know there are places where there is no network … (laughs) you see at my granny's place, there is no network it's just some odd area right (laughs).* [Female adolescent living with HIV, aged 18.]

Discussion

Principal Findings

The study findings suggest that mobile phone access among adolescents living with HIV in Eswatini may be high, although this was a small qualitative sample, providing a potentially solid foundation for the implementation of mHealth interventions targeting this age group. Currently, mHealth use in the country is largely limited to calls and SMS text message reminders for clinical appointments sent by health care workers [9]. There may be opportunities to expand the scope of mobile phone–based interventions among adolescents.

Older adolescents reported owning smartphones, while younger adolescents often shared phones with siblings or caregivers. This suggests the need for tailored age-appropriate mHealth solutions, with younger adolescents requiring simpler, lower-bandwidth tools compatible with feature phones and shorter usage durations due to parental control, while older adolescents could benefit from more interactive, internet-based interventions as observed in a study conducted in Zimbabwe [38]. However, while smartphone ownership is critical for implementing internet-based mHealth solutions, such interventions require stable internet connectivity, which may be hindered by limited coverage, slow internet speeds, and high costs [38]. This is particularly important in Eswatini, where network and internet access remain limited in some places in the country [39]. As of 2024, only 50.3% of the population had internet access, and the cost of 1 GB of mobile data was US $5.82 [39]. Therefore, given that 58.9% of the population lives below US $3.65 per person per day, mHealth interventions requiring regular internet use should be implemented cautiously to avoid excluding lower-income users [40].

Additionally, phone usage patterns varied by age. All adolescents used phones primarily for calls, while older adolescents were more likely to engage with social media platforms too. This underscores the importance of designing mHealth interventions with adaptable features that align with adolescents' communication habits and preferences [41]. For instance, a study in Uganda found that adolescents preferred not only voice calls but also SMS text messaging and WhatsApp messaging, highlighting the potential value of integrating social connectivity features into mHealth interventions [41]. However, such features should be used with caution in Eswatini due to the cost of mobile services. As of 2024, calls cost approximately US $0.07 per minute, while an SMS text message cost US $0.02 in Eswatini [39].

The study further identified 3 core themes: feasibility, desired qualities, and potential concerns, which are vital to informing the design of gamified interventions. These themes offer valuable insights into the practicality and acceptability of such interventions.

In terms of feasibility, participants expressed confidence in the potential of mHealth, particularly mobile games, to improve ART adherence, despite only a quarter having prior gaming experience. This highlights the importance of considering players' prior experience in the design of gamified interventions. According to Fitzgerald et al [42], games that promote user engagement are typically those that are easy to play, intuitive, and do not require previous gaming skills or knowledge [42]. This is supported by Sardi et al [43], who emphasized that effective games should be adaptive, offering various modes of play to accommodate different player types and skill levels [43]. Consequently, involving users in the design process is critical to ensure that the resulting intervention is user-centered and tailored to their needs, preferences, and abilities [43]. Additionally, the selection of appropriate gaming elements or mechanics is crucial, as these features can significantly influence user engagement and motivation. For instance, storytelling or narrative elements help set clear expectations and create an immersive experience that puts players at ease, enhancing their willingness to engage with the game [44]. Other mechanics, such as onboarding tutorials, rewards, and leaderboards, have been shown to promote sustained engagement by guiding new players and offering in-game incentives that reinforce continued participation [44,45]. Despite participants' limited prior exposure to gaming, existing evidence supports the effectiveness of gamified mHealth interventions in improving medication adherence among adolescents [19]. These findings highlight the feasibility and potential impact of well-designed, user-centered gamified tools in supporting ART adherence among adolescents living with HIV.

Regarding the desired features or qualities of the gamified intervention, the study highlighted the importance of aligning game content and features with the preferences and needs of end users. First, participants emphasized that effective gamified interventions must include relevant, accurate, and engaging educational content, particularly on HIV and the benefits of ART. This finding aligns with a study conducted among adolescents living with HIV in the United States, where the integration of health education into games improved knowledge retention and supported positive behavior change while maintaining user engagement [46].

Second, the study revealed that incorporating a strong support system within the intervention could enhance its effectiveness in promoting ART adherence. Participants identified support in the form of medication reminders and opportunities for networking with other adolescents as essential. Literature consistently highlights the value of such support in improving ART adherence among adolescents living with HIV [47,48]. In

XSL•FO
RenderX

a gamified context, support can be delivered through features such as in-game pop-up messages reminding players of important health behaviors or through social connectivity that allows users to share progress and communicate with peers. Platforms such as social media can offer avenues for users to exchange experiences, provide encouragement, and reinforce positive behaviors. However, the inclusion of social features must be approached with caution. Participants expressed concern that social connectivity within the game could compromise their privacy and lead to unintended disclosure of their HIV status. This concern is echoed in broader literature, where privacy and confidentiality have been flagged as critical risks in mHealth interventions that incorporate social connection and collaboration features [45,49]. Although social connectivity ranks as the second most frequently used game element, it raises substantial concerns about exposing players' identities, particularly among vulnerable populations such as adolescents living with HIV [45]. These findings emphasize the need to design stigma-sensitive and developmentally appropriate interventions [49]. Adolescence is a period marked by emotional and cognitive maturation, yet formal reasoning and risk assessment abilities may still be developing [50].

Therefore, developers must carefully evaluate whether and how to include socially driven elements. Recommended approaches include the use of anonymous avatars and nicknames, while disabling features such as voice and video calls, and restricting media sharing strategies successfully implemented in the design of the PEERNaija game [51]. In the context of Eswatini, the findings suggest that integrating gamified mHealth interventions into existing service delivery structures, such as Teen Clubs, could enhance both effectiveness and user safety. Teen Clubs are trusted, adolescent-friendly platforms that provide safe spaces for sharing experiences and peer support without compromising privacy [52]. Leveraging peer educators within these settings could further enhance the intervention's reach and acceptability [52].

Finally, regarding potential concerns, the study highlighted the critical importance of privacy and confidentiality in the design of gamified interventions. Participants expressed concerns about the risk of unintended disclosure, particularly among younger adolescents who often share mobile phones with siblings or caregivers. Such unintended disclosure could lead to stigma and discrimination, which are well-documented barriers to ART adherence among adolescents living with HIV [53]. Therefore, the game's design, including its name, features, and interface, must be carefully considered to prevent any breach of confidentiality that could negatively affect adolescents' willingness to engage with the intervention [54].

In addition to privacy concerns, participants raised issues related to the financial burden of mobile gaming and limited access to network services. These concerns underscore the need to critically evaluate the economic feasibility of mHealth interventions in low-resource settings. Adolescents must not only own a mobile phone, ideally a smartphone, but also maintain consistent access to mobile data and internet services. This requirement presents a significant challenge in contexts such as Eswatini, where economic constraints and infrastructural barriers, such as poor network coverage, limited electricity, and low digital literacy, can impede the successful implementation of mHealth solutions [38]. Similar challenges have been observed in other low-income settings, where the high cost of smartphones and internet bundles has contributed to poor uptake and limited effectiveness of mHealth-based interventions [38,41,55]. To mitigate these barriers, recent innovations in offline mobile gaming have shown promise. Offline games eliminate the need for constant internet access, thereby reducing the financial burden on users and improving accessibility. Studies have shown that offline interventions are associated with higher uptake and more favorable outcomes, particularly in resource-limited environments [56]. As such, the development of offline gamified interventions could represent a practical and sustainable solution to improve ART adherence among adolescents living with HIV in Eswatini and similar contexts [57].

Nevertheless, for mHealth interventions to be applicable, engaging, feasible, and effective, they should be firmly grounded in behavior change theories [58]. These theories provide a comprehensive framework for understanding adolescent behavior, particularly during the adolescence stage, a developmental period characterized by significant psychological, social, and physiological changes that can influence ART adherence [50,59]. By applying these theories, designers can identify key determinants of adherence and gain valuable insights into how behavior change can be effectively promoted [50]. Behavior change theories also inform the selection of appropriate game elements and design features that resonate with adolescents' needs and preferences, thereby ensuring that user concerns are addressed during the design process [58]. Furthermore, they guide the integration of behavior change techniques that can enhance the intervention's overall impact on ART adherence [50,58,59].

Critically, involving adolescents in the design process is essential. Their participation enables the cocreation of game features that directly reflect their lived experiences, needs, and expectations, thereby increasing the likelihood of sustained engagement and intervention effectiveness [59]. Health behavior models, such as social cognitive theory, the information-motivation-behavioral (IMB) skills model, and motivational interviewing, have been widely applied in mHealth interventions targeting adolescents [50]. These models conceptualize ART adherence as a behavior influenced by a combination of accurate information, individual and social motivation, and the acquisition of behavioral skills. When applied effectively, they enhance adolescents' self-efficacy and lead to improved ART adherence outcomes [50]. Thus, grounding intervention design in these theories, developers can ensure that components are aligned with adolescents' realities and are both contextually relevant and capable of promoting sustainable behavior change [50,58].

Limitations and Strengths

A key limitation of this study is that it only included adolescents from one region of the country, specifically those who are members of Teen Clubs. Additionally, the small sample size is not representative of all adolescents living with HIV in the country or even within the Hhohho region. As a result, the

XSL•FO
RenderX

findings cannot be generalized to all adolescents in Eswatini. Despite these limitations, this study is the first to explore and describe mobile phone access, usage patterns, and perspectives on gamified interventions among Swati adolescents living with HIV. The findings provide valuable baseline data and serve as a foundation for future research aimed at developing and evaluating gamified interventions to enhance ART adherence among adolescents living with HIV.

Conclusion

The study indicates that mobile phone access may be high among adolescents living with HIV in Eswatini, with the majority using their phones daily for various purposes. A considerable proportion of participants expressed a belief in the feasibility of gamified interventions to support ART adherence, highlighting the importance of supportive, educational, and privacy-assured features. Nonetheless, concerns related to confidentiality and economic barriers must be addressed to ensure the successful implementation and long-term sustainability of such interventions.

Given the promise of mHealth interventions, future research should focus on the co-design of gamified interventions rooted in behavior change theories to ensure alignment with their behavioral characteristics, preferences, and lived experiences. These interventions should also be rigorously evaluated for their effectiveness within the Swati context and considered complementary strategies within existing Ministry of Health programs aimed at improving HIV-related outcomes among adolescents.

Abstract

Background: Digital tools are known to promote public health interventions such as vaccine delivery. The recommendation that health care professionals (HCPs) use vaccination-related mobile apps or web-based applications has contributed to improving vaccine awareness and acceptance in the United States. The state of Texas, which has one of the lowest human papillomavirus (HPV) vaccination rates, has seen a significant increase in HPV vaccine hesitancy, particularly during the COVID-19 pandemic.

Objective: This study aimed to examine the association between changes in HPV vaccine hesitancy observed by HCPs among patients in Texas and promotion of vaccination-related applications at the health care facilities where they practiced during the COVID-19 pandemic.

Methods: A population-based cross-sectional survey was administered in 2021 by the MD Anderson Cancer Center to HCPs working in Texas using email addresses obtained from the LexisNexis Master Provider Referential Database. HCPs were asked if they assessed HPV vaccination status during every patient encounter. Those who responded "Often/Always" or "Sometimes" were subsequently asked whether they observed any change ("Decreased," "No change," "Increased," or "Not sure") in HPV vaccine hesitancy during the COVID-19 pandemic. Additionally, HCPs were asked whether their practice offers HPV vaccination. Those who responded "Yes" to this question were further asked whether vaccination-related applications are promoted at the facility where they practice, with response options being "Yes," "No," or "I don't know." Logistic regression analysis was performed to examine the association between changes in HPV vaccine hesitancy observed by HCPs and promotion of vaccination-related applications at the facility where they practice.

Results: A total of 1283 HCPs completed the survey. Of the 730 HCPs who observed changes in HPV vaccine hesitancy, 51 (7%) reported a decrease in their patients' HPV vaccine hesitancy. Of these 730 HCPs, 578 (79.2%) responded to the questions regarding vaccination-related applications, of whom 104 (18%) reported that vaccination-related applications were promoted at their facilities. Compared to HCPs who reported not promoting vaccination-related applications, those who reported doing so at their facilities had significantly higher odds of observing a decrease in HPV vaccine hesitancy among patients (adjusted odds ratio [aOR] 2.48, 95% CI 1.10-5.55; *P*=.03). HCPs working at federally qualified health centers or city, county, or public health care facilities (aOR 4.02, 95% CI 1.33-12.14; *P*=.01) and HCPs who administered the HPV vaccine under standing orders at their facilities (aOR 2.91, 95% CI 1.11-7.63; *P*=.03) had significantly higher odds of observing a decrease in HPV vaccine hesitancy at their practices.

Conclusions: Our findings suggest that promoting vaccination-related applications at health care facilities in areas with high HPV vaccine hesitancy such as Texas could further decrease HPV vaccine hesitancy in the population. This may be potentially applicable across diverse health care settings, particularly in the context of pandemic preparedness.

Introduction

In the United States, approximately 47,984 new cases of human papillomavirus (HPV)–associated cancers are diagnosed annually, including 26,280 cases among women and 21,704 cases among men [1]. Despite the availability of safe and effective HPV prophylactic vaccines that can help prevent these cancers and the adoption of a standardized recommendation schedule in the United States [2-5], HPV vaccination uptake remains suboptimal due to barriers including lack of knowledge, concerns about safety and efficacy, and cost concerns [6,7]. In response, government agencies have made efforts to improve HPV vaccination coverage through school- and community-based vaccination programs, health care professional (HCP)–based interventions, and cost reduction initiatives [8]. Since it was approved in the United States, the HPV vaccine was included in the Vaccines for Children program, which provides free vaccines to uninsured or underinsured children until the age of 18 years [9-11]. Additionally, the Affordable Care Act mandates that private health insurers cover vaccines recommended by the Advisory Committee on Immunization Practices, including HPV, and are prohibited from charging copays or deductibles for these vaccines when administered by in-network HCPs [12]. Despite these efforts, HPV vaccination coverage among adolescents aged 13 to 17 years was only 62.9% in 2024, which is far below the Healthy People 2030 goal of achieving 80% vaccination coverage [7,13,14].

According to the World Health Organization, vaccine hesitancy, one of the major threats to public health, is defined as a delay in accepting or refusal of safe and effective vaccines despite their availability [15,16]. In the context of HPV vaccination, vaccine hesitancy constitutes a significant barrier to both initiating and completing the HPV vaccination series [17]. The most common reasons for vaccine hesitancy are limited knowledge; beliefs that vaccination is unnecessary; concerns about vaccine safety and potential side effects; and a lack of strong, presumptive HCP recommendations [18-23]. A few studies have shown the benefits of using digital interventions to reduce vaccine hesitancy by increasing public awareness and knowledge and intentions to receive the HPV vaccine [24,25]. A quantitative study conducted among 20 adolescents and 34 parents in Philadelphia, Pennsylvania, assessed the effectiveness of the Vaccipack app, which included a vaccine tracker, inspirational stories, and an active discussion forum, designed to promote intention to receive the HPV vaccine [26]. This app, based on an integrated behavioral model, was found to have high acceptability among parents (88%) and adolescents (75%) and to be beneficial for them (82% and 85%, respectively) [26]. Another qualitative study assessing the Vax4HPV mobile app designed based on the social ecological theory was conducted among parents of children and adolescents aged 9 to 14 years in Connecticut to evaluate its benefits in reducing HPV vaccine hesitancy through informed decision-making [27]. This study reported that the implementation of this theory-based, user-centered app helped mitigate hesitancy by bridging the gap between intention to vaccinate and vaccine uptake [27]. Participants reported that the Vax4HPV app provided gender-neutral information, stronger HCP recommendations, and information on clinics providing free vaccination or scheduling appointments [27]. Additionally, a study conducted in New Mexico among 82 parents of vaccine-eligible teenagers found that mobile apps such as Vacteens reduced vaccine hesitancy among parents and their adolescent daughters aged 11 to 14 years [28]. Similarly, a clinic-based study conducted in Houston, Texas, reported that the HPVCancerFree app served as an adjunct during health care visits, providing education and support to help parents make evidence-based decisions about HPV vaccination [29]. A randomized trial among 209 parents and their sons aged 11 to 14 years evaluated the effectiveness of a tailored and engaging mobile app (TeenVac) compared to the Centers for Disease Control and Prevention (CDC) HPV vaccination pamphlet available online [30]. This study showed that using the TeenVac app led to higher completion of the HPV vaccine series than using the pamphlet [30].

Texas is the second-largest state in the United States, with one of the lowest up-to-date HPV vaccination rates (52.2%) across the country [31]. Access to preventive health care during the COVID-19 pandemic was impacted due to closed medical offices, limited availability of appointments, and concerns regarding contracting COVID-19 [32]. A study conducted among 252 parents at a children's hospital in California reported increased hesitancy regarding childhood vaccines during the COVID-19 pandemic [33]. Furthermore, a survey conducted among HCPs in Texas found that 17.1% of HCPs reported an increase in HPV vaccine hesitancy, whereas another study of pediatricians in Massachusetts found that 11% of pediatricians reported an increase in parental HPV vaccine hesitancy during the pandemic [34,35]. Compared to 2018 and 2019, substantially fewer childhood (9-12 years) and adolescent (13-17 years) vaccines were administered from March 2020 to September 2020 (ie, during the acute phase of the COVID-19 pandemic) [36]. While prior studies have reported the benefits of HPV vaccination–related applications outside major outbreaks or public health emergencies [26-29], little is known about the role that these applications may play during outbreaks such as COVID-19 or other pandemics. In this study, we examined the association between the promotion of vaccination-related applications at health care facilities and changes observed by HCPs regarding HPV vaccine hesitancy during the COVID-19 pandemic. We hypothesized that HCPs who reported promoting vaccination-related applications at their health care facilities had higher odds of observing a decrease in HPV vaccine hesitancy. Grounded in the diffusion of innovation theory, this study's findings will support the integration of digital health interventions into the package of pandemic preparedness activities in the United States.

Methods

Study Design, Data Source, and Population

We conducted a population-based cross-sectional study using data from a statewide survey collected between January 2021 and April 2021 by the University of Texas MD Anderson Cancer Center. This survey was developed to evaluate Texas-based HCPs' knowledge, perceptions, and practices regarding the HPV vaccine recommendation and was administered electronically in English and Spanish using all email addresses obtained from the LexisNexis Master Provider Referential Database [37]. The survey was sent via REDCap (Research Electronic Data Capture; Vanderbilt University) to Texas-based HCPs practicing family medicine, internal medicine, pediatrics, and gynecology; physician assistants; and nursing staff who held a current Texas license and for whom email addresses were available in the LexisNexis database. Up to 3 email reminders were sent to each participant. In case the survey was not completed after the initial invitation, the first follow-up email was sent on the eighth day (–2 to +2 days) from the initial invitation, the second follow-up email was sent on the eighth day (–2 to +2 days) from the first follow-up email, and the third follow-up email was sent 5 days (–2 to +2 days) after the second follow-up email. The estimated time to complete the survey was 10 minutes. A total of 1283 HCPs completed the survey, with a response rate of 7% (1283/18,328). To report this study, we adhered to the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines to ensure ethical and scientific integrity (Checklist 1) [38].

Ethical Considerations

This study was approved by the University of Texas MD Anderson Cancer Center Ethical Review Board (protocol 2019-1257). Participation in this study was voluntary and confidential. All participants provided informed consent. The dataset underwent deidentification through the removal of all identifiable information. Each participant received a US $10 gift card for completing the survey. Additionally, after completing the survey, participants were entered into a draw for a US $1000 Amazon gift card, which was held 3 months after the survey closed.

Measures

Dependent Variable: Changes in HPV Vaccine Hesitancy Among Patients Observed by HCPs During the COVID-19 Pandemic

We examined the changes in HPV vaccine hesitancy observed by HCPs among patients during the COVID-19 pandemic. To capture the subjective impression of hesitancy, HCPs were asked the following: "At every patient encounter, do you assess HPV vaccination status?" Those who answered "Sometimes" or "Often/Always" were further asked the following: "During the COVID-19 pandemic, I have observed that HPV vaccination hesitancy..." The possible responses were "Decreased," "Increased," "No change," and "Not sure." We coded "Decreased" as 1 and "Increased or no change" as 0. Those who responded "Not sure" were excluded from this study. The reference category was defined as "Increased or no change."

Independent Variable: Promotion of Vaccination-Related Applications at the HCPs' Facilities of Practice

For this variable, HCPs were first asked the following: "Does your practice offer HPV vaccination?" Those who answered "Yes, always offered" or "Yes, but not consistently" were assessed for promoting vaccination-related applications at their facilities using the survey question "Which of the following is practiced at your facility? ...Promote vaccination-related apps," with possible responses of "Yes," "No," and "I don't know." The reference category was "No."

HCP-Related Variables (Covariates): HCPs' Sociodemographic Variables and Practice-Related Factors

We included HCPs' age (<35 years, 35 to 54 years, and ≥55 years), sex (male and female), race and ethnicity (non-Hispanic White, non-Hispanic Black, Asian, Hispanic, and other), location of practice (rural and urban) and type of facility (university hospital, teaching hospital, affiliated clinic, or employed physician practices; Federally Qualified Health Center [FQHC] or city, county, or public health care facility; or other), administration of HPV vaccination under standing orders (yes or no), use of reminders (eg, phone or mail) when HPV vaccination was due ("Yes," "No," and "I don't know"), and use of recalls (eg, computerized tracking) when HPV vaccination was past due ("Yes," "No," and "I don't know"). On the basis of the 2013 Rural-Urban Continuum Codes, we classified the location of practice for the HCPs using the zip codes of their workplaces, with Rural-Urban Continuum Codes 1 to 3 classified as urban and 4 to 9 classified as rural [39].

Patient-Related Variables: Patients' Sociodemographic Factors

As we did not collect data from patients directly, patient-related variables were obtained from the 2022 American Community Survey 5-year database [40], which allowed us to determine the race and ethnicity of the population residing in Texas at the level of the zip code where the HCPs practiced. This variable was also included in our model as a potential predictor of changes in HPV vaccine hesitancy observed by HCPs among their patients [41].

Data Analysis

Descriptive statistics were used to estimate the prevalence of promoting the use of vaccination-related applications at the HCPs' facilities and HCP- and practice-level factors stratified by HCPs' observed changes in HPV vaccine hesitancy during the COVID-19 pandemic. To that end, we used frequencies, weighted percentages, 95% CIs, and the Pearson chi-square test or Fisher exact test as appropriate. Bivariate and multivariable logistic regression analyses were used to determine the odds of observed decrease in HPV vaccine hesitancy reported by HCPs and the promotion of vaccination-related applications during the COVID-19 pandemic. In the multivariable logistic regression model, we adjusted for HCPs' age, sex, race and ethnicity, practice location, type of facility, administration of HPV vaccination under standing orders, use of reminders (eg, phone or mail) when HPV vaccination was due, use of recalls (eg, computerized tracking) when HPV vaccination was past due,

XSL•FO
RenderX

and predominant zip code–level race and ethnicity of patients. Descriptive analyses were conducted using the full sample (n=730), whereas regression analyses were based on a reduced sample (n=576) due to missing data for one or more covariates. However, for each covariate with missing data, a "missing" category was created and included in the logistic regression. We considered *P* values <.05 to be statistically significant, and all tests were 2 sided. We conducted our analysis using SAS (version 9.4; SAS Institute).

Results

Demographic Characteristics

Overall, 1283 HCPs completed the survey, with a mean age of 47.1 (SD 11.3) years. Of the 730 HCPs who responded to the survey question about changes in HPV vaccine hesitancy, 51 (7%) reported observing a decrease in HPV vaccine hesitancy, whereas 679 (93%) observed an increase or no change among patients during the COVID-19 pandemic (Table 1). Of the 730 HCPs, 578 (79.2%) responded to the survey question about promoting vaccination-related applications, of whom 104 (18%) reported promoting them at their practices. A higher proportion of HCPs included in this study were aged 35 to 54 years (441/705, 62.6%), female (556/719, 77.3%), non-Hispanic White individuals (369/730, 50.5%), and urban dwellers (699/729, 95.9%). In addition, 50.1% (282/563) used standing orders, 46.3% (274/592) used reminders, and 41% (244/595) used recalls at their facilities to remind eligible individuals to receive the recommended vaccines (Table 1). A higher proportion of HCPs included in this study practiced in zip codes with predominantly non-Hispanic White populations (424/636, 66.7%), followed by those with predominantly Hispanic populations (171/636, 26.9%; Table 1).

The proportion of HCPs who observed a decrease in HPV vaccine hesitancy among patients was higher among those who promoted vaccination-related applications (13/104, 12.5%); those who were aged 55 years or older (15/185, 8.1%), female (41/556, 7.4%), and Hispanic (13/108, 12%); those practicing in rural locations (4/30, 13.3%); those working at FQHCs or city, county, or public health care facilities (15/99, 15.2%); and those using standing orders (23/282, 8.2%) or reminders (18/274, 6.6%; Table 1). A higher proportion of HCPs who observed a decrease in HPV vaccine hesitancy practiced in zip codes with predominantly Hispanic populations (16/171, 9.4%; Table 1).

Relationship Between Promotion of the Use of Vaccination-Related Applications at HCPs' Facilities and Observing a Decrease in HPV Vaccine Hesitancy Among Patients

Compared to HCPs who did not report promotion of vaccination-related applications at their facilities, those who did had significantly higher odds of observing a decrease in HPV vaccine hesitancy among patients during the COVID-19 pandemic (adjusted odds ratio [aOR] 2.48, 95% CI 1.10-5.55; *P*=.03; Table 2). Additionally, compared to HCPs working at university hospitals, teaching hospitals, affiliated clinics, or employed physician practices, HCPs working at FQHCs or city, county, or public health care facilities had significantly higher odds of observing a decrease in HPV vaccine hesitancy among patients during the COVID-19 pandemic (aOR 4.02, 95% CI 1.33-12.14; *P*=.01; Table 2). Compared to HCPs who did not administer the HPV vaccine under standing orders at their facilities, those who did had significantly higher odds of observing a decrease in HPV vaccine hesitancy among patients (aOR 2.91, 95% CI 1.11-7.63; *P*=.03; Table 2).

We did not find a statistically significant association between observed decrease in HPV vaccine hesitancy during the COVID-19 pandemic reported by HCPs and HCPs' demographic characteristics, such as age, sex, race and ethnicity, location of practice, and use of reminders or recalls at their facilities, as well as patient-related characteristics, such as zip codes with predominantly non-Hispanic White, non-Hispanic Black, and Hispanic populations in which the HCPs practiced (Table 2).

Discussion

Principal Findings

In this population-based study, we found that HCPs working in Texas who promoted vaccination-related applications at their facilities had higher odds of observing a decrease in HPV vaccine hesitancy among patients during the COVID-19 pandemic. Our study findings align with those of previous studies reporting the benefits of vaccination-related mobile apps in decreasing HPV vaccine hesitancy and thereby increasing vaccine uptake [24-29]. Recent studies have reported a rise in HPV vaccine hesitancy and decreased vaccine uptake following the COVID-19 pandemic in the United States [33-35,42]. As the HPV vaccine is safe and effective in preventing HPV-associated cancers [2,5], and considering that digital interventions have been proven effective at increasing HPV vaccine awareness and knowledge [24,25], there is a need to promote vaccination-related applications to increase awareness and knowledge and address misinformation about the HPV vaccine.

Previous studies have reported that the most common reasons for HPV vaccine hesitancy are safety concerns and lack of knowledge and absence of HCP recommendation among parents of vaccine-eligible children and among age-eligible adults, respectively [43,44]. A positive association was found between HCPs' knowledge of the HPV vaccine and initiation and completion of the vaccine series [45]. When HCPs are well informed, they can confidently communicate vaccine benefits and respond to parental concerns, which is critical for building trust and influencing vaccination decisions [46]. Mobile apps have helped users access immunization-related information, create and track vaccination schedules, and locate clinics where the public can receive vaccines [47,48]. Prior studies have focused on using mobile apps to promote HPV vaccination–related information, some of which are publicly available whereas others are still being evaluated as part of research projects. Among the mobile apps under evaluation in research studies, Vaccipack, Vacteens, Vax4HPV, HPVCancerFree, and TeenVac have demonstrated their potential to decrease HPV vaccine hesitancy [26-30]. Thus, integrating vaccination-related mobile apps into clinical practice could be a valuable tool for promoting HPV vaccination and reducing hesitancy. Furthermore, timely reminders sent by mobile apps to vaccine-eligible individuals about their vaccination dates align with the transtheoretical model of behavior change, which posits that behavior change is a gradual process that occurs in stages [49]. By providing reminders to vaccine-eligible individuals, these vaccination-related apps motivate them to move from contemplation to action, thereby improving HPV vaccination uptake [49]. The US CDC developed a publicly available app called CDC Vaccine Schedules to provide HCPs and patients with immediate access to comprehensive information on vaccine recommendations, including immunization schedules, precautions, and contraindications [50]. Other publicly available immunization-related apps include ACOG, developed by the American College of Obstetricians and Gynecologists; HPV Vaccine: Same Way, Same Day, developed by the Academic Pediatric Association and American Academy of Pediatrics; and Vaccines on the Go: What You Should Know [51]. Despite the variety of official vaccination-related applications available to HCPs, we found that a small proportion (104/578, 18%) of Texas-based HCPs promoted HPV vaccination–related applications at their health care facilities.

We also found that HCPs working at FQHCs or city, county, or public health care facilities had higher odds of observing a decrease in HPV vaccine hesitancy among patients than those working at university hospitals, teaching hospitals, affiliated clinics, or employed physician practices. This could be attributed to the greater availability of preventive health care services, such as HPV vaccination, at public facilities, which provides an opportunity for HCPs working at such practices to further counsel patients and recommend vaccination applications [52,53]. A study conducted among HCPs serving minority and low-income populations identified a lack of preventive care visits as a barrier to HPV vaccine recommendation [54]. Given that FQHCs primarily offer health care services to uninsured and low-income patients, they play a critical role in increasing the HPV vaccination uptake among socioeconomically disadvantaged populations [55]. Adolescents from more educated and higher-income households show higher rates of HPV vaccine hesitancy [56]. On the other hand, adolescents with lower income levels have higher odds of completing the HPV vaccine series [57]. These findings highlight the need for organizational policies or protocols to strengthen access to HPV

XSL•FO
RenderX

vaccination, improve patient counseling, and reduce vaccine hesitancy.

We found that HCPs who reported using standing orders for HPV vaccination at their facilities had higher odds of observing a decrease in HPV vaccine hesitancy among their patients. Standing orders authorize nurses, pharmacists, and other trained HCPs, as permitted by state law, to assess a patient's immunization status and administer vaccines in accordance with a preapproved protocol established by the medical director, physician, or other authorized practitioner [58]. A 2022 study conducted among 16 nurses, medical assistants, and HCPs working in primary care settings in the United States found that implementing standing orders for HPV vaccination increased nurses' and medical assistants' autonomy [59]. This approach led to improved access to the HPV vaccine, fewer missed opportunities, earlier vaccination, and normalization of HPV vaccination as a routine part of care [59]. As standing orders have been shown to be effective at increasing vaccination rates [60], they may be particularly effective in addressing HPV vaccine hesitancy by ensuring timely, consistent, and standardized HPV vaccination practices across health care facilities.

Strengths and Limitations

The major strength of our study is the inclusion of HCPs from diverse backgrounds and specialties. While it offers critical insights into the benefits of digital interventions during the COVID-19 pandemic, our study is not without limitations. First, we could not infer causality because the study was cross-sectional. Second, a small proportion of HCPs practicing at the health care facilities who responded to the survey observed decreases in HPV vaccine hesitancy, which may have reduced the power of our statistical analysis. This small sample size also limits the generalizability of our findings and increases the risk of falsely rejecting our study hypothesis. Third, Texas has a unique sociopolitical landscape regarding vaccine attitudes, as well as a distinct population racial, ethnic, and age distribution, limiting the generalizability of our findings to other US regions. Fourth, there is potential for information bias as changes in HPV vaccine hesitancy were self-reported and based on HCP recall. Fifth, the study question does not allow us to specify the types of applications being promoted or the mode of promotion: active (eg, discussed with patients), passive (eg, posters), or both. Sixth, we did not include HCPs comfort with digital tools, patients' socioeconomic status, and institutional culture as covariates in our study as such information was not available. Finally, the sampling frame derived from the LexisNexis database may not fully cover all Texas-based HCPs as some HCPs may have been missing from the database or lacked an email address, potentially limiting the generalizability of the findings.

Conclusions

This study demonstrated the added value of mobile apps in reducing HPV vaccine hesitancy in Texas. Our findings have implications for designing and implementing tailored digital interventions to successfully counter misinformation about HPV vaccination, especially during major outbreaks such as the COVID-19 pandemic. Future prospective studies could explore the long-term impact of these vaccination-related mobile apps in reducing missed opportunities and increasing HPV vaccination uptake among age-eligible individuals.

Acknowledgments

The authors want to thank the Texas health care professionals for participating in the study. Generative artificial intelligence was not used in any portion of manuscript writing.

Funding

The study was funded by the National Cancer Institute (P30CA016672 to S Shete), the Betty B. Marcus Chair in Cancer Prevention (awarded to S Shete), and the Duncan Family Institute for Cancer Prevention and Risk Assessment (awarded to S Shete). The funders were not involved in the study design, data analysis and interpretation, or manuscript writing.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Abstract

Background: Mobile health (mHealth) apps are widely available, and some have proven safe and effective for management of specific chronic conditions. Despite a high degree of interest, the potential of these technologies has yet to be realized. Patient and clinician attitudes are key factors that influence the adoption of mHealth apps but remain poorly understood, particularly in the United States.

Objective: This study aimed to identify both patient and clinician attitudes that can influence recommending and adopting mHealth apps.

Methods: Using well-established technology adoption and implementation science frameworks, this study included a deductive content analysis using a rapid qualitative analytic method. Semistructured interviews were conducted with patients and clinicians to identify technical and material, social and personal, and policy and organizational factors that can influence the recommendation or adoption of mHealth apps. The interviews and data analysis were performed between September 2023 and August 2024.

Results: Participants included 20 clinicians (n=12, 60% general internists) with a mean time in practice of 17 (SD 11.6) years, and 28 patients with a mean age of 59 (SD 12.1) years. A total of 7 categories related to patients' and clinicians' attitudes toward mHealth apps emerged: (1) apps as tools to improve health by extending care, (2) the role of apps in enhancing the patient–clinician relationship, (3) the need for simplicity and efficiency in app design, (4) the influence of prior experience with mHealth apps, (5) comfort with technology, (6) recommendations from trusted sources, and (7) education and hands-on experience. Although similar factors were considered by patients and clinicians, their views about older adults' interest and ability to use mHealth apps differed.

Conclusions: Understanding patient and clinician views about mHealth apps provides critical insights for developing approaches to facilitate their use. These findings suggest patients and clinicians share similar views about the benefits of mHealth apps. Nonetheless, clinicians' perceptions about older patients' interest and ability to use mHealth apps may negatively impact recommendation of mHealth apps and subsequent adoption by older adults.

mobile health; mHealth; digital health technology; mhealth apps; health apps; qualitative

Introduction

Mobile health (mHealth) apps can collect health information to facilitate monitoring of patients' health and behaviors throughout the day and provide real-time, personalized recommendations at key decision points (eg, when making dietary decisions). mHealth apps can increase physical activity [1] and address conditions such as depression, anxiety [2], tobacco use [3], and alcohol use disorder [4].

There are over 350,000 mHealth apps available in app stores [5], and nearly two-thirds of US adults report use of an app for health-related purposes [6]. The global mHealth market was valued at US $83.17 billion in 2023 and is expected to grow to US $249.05 billion in 2032 [7]. Despite enthusiasm for app use,

XSL•FO
RenderX

adoption has lagged in underserved populations and among persons with chronic conditions [8,9]. With an increasing life expectancy [10], increased burden of chronic diseases in the United States [11], and persisting barriers to health care access [12], mHealth apps have the potential to improve health outcomes by offering the convenience of readily available health care solutions.

Getting safe and effective apps into the hands of people who need them most, and sustaining use of these apps remains a challenge. For instance, older aged persons, women, and those with lower educational attainment are less likely to use apps, and the reasons for these disparities are unknown [13]. Additionally, it has been estimated that approximately 71% of app users discontinue use within about 90 days [14]. Further, many clinicians either recommend mHealth apps inconsistently or they do not recommend them at all [15-17].

There are technology level, individual level (eg, patient and clinician), organization level, and policy level factors that may impact the adoption of mHealth apps, with each of these factors influencing the other(s) to varying degrees [18-21]. Studies have shown that patient and clinician attitudes about mHealth apps are amongst the most influential factors that determine mHealth app use [18,21,22]. In a study by Vo et al [23], patients identified patient engagement and patient empowerment as potential strengths of mHealth apps, and trustworthiness, limited personalization (eg, relevance to their condition, culture, and accessibility) as potential weaknesses. Sarradon-Eck and colleagues [24] showed that general practitioners in France had mixed views about mHealth apps, with some adopting a favorable view and others expressing skepticism or resistance. As an example, the main perceived benefit expressed by clinicians was related to the apps' potential to facilitate completion of their work and follow-up care because of the reliable and objective measurements provided by apps. Clinicians have also expressed concerns about mHealth apps negatively impacting the patient–clinician relationship because they could lead to decreased face-to-face interactions [25]. Additionally, in a study by Dahlhausen and colleagues [26], clinicians identified their ability to effectively advise patients on their use of mHealth apps, insufficient evidence supporting use and liability as concerns.

A small number of studies have explored the views of both patients and clinicians simultaneously. For example, Byambasuren and colleagues [27] conducted semistructured interviews of general practitioners and patients to identify determinants of prescribing mHealth apps in Australian general practice settings. General practitioners identified generational differences, limited knowledge of apps that can be prescribed and trustworthy sources to access them, time required to learn to use apps, concerns about privacy, and safety and trustworthiness as potential barriers. The main barriers identified by patients were older age and usability of mHealth apps. Importantly, patients did not share clinicians' concern about data privacy and data safety, highlighting an opportunity to develop a shared understanding of these potential barriers. Jezrawi et al [28] conducted surveys of both patients and physicians, as well as focus groups with patients to understand their attitudes about mHealth apps. Physicians who prescribed apps to patients relied most on personal opinions and recommendations from patients, whereas recommendations from trusted medical organizations or doctors were the most frequently cited sources that patients considered when making decisions about an mHealth app.

Even fewer studies have directly compared the views of patients and clinicians. For instance, to understand patients' and clinicians' perceptions about mHealth apps, Liu and colleagues [29] conducted semistructured interviews with 9 patients and 14 clinicians and triangulated their data to generate 5 themes, including 1 theme indicating different concerns between the 2 groups related to mHealth apps. For example, patients were more concerned about the effectiveness of mHealth apps, and clinicians were most concerned about the usability of mHealth apps. In another study, Barber and colleagues [30] conducted semistructured interviews to elicit patients' and physicians' perspectives on the use of an mHealth app for management of osteoarthritis. Investigators found that patients were supportive of app use, but physicians were more skeptical.

While the United States has contributed more mHealth-related research than any other country in the world [31], most research specifically investigating patients' and clinicians' broader attitudes about mHealth apps is based outside of the United States [19,23,24,26,27,32-42]. This is important because non-US countries may have regulatory requirements that influence attitudes in ways that are not relevant to US consumers and clinicians [43-45]. Moreover, realizing the potential of mHealth apps to improve health outcomes requires an understanding of both the individual and shared attitudes of patients and clinicians about mHealth. This understanding may facilitate the development of interventions to foster a shared mental model about the strengths and limitations of mHealth apps to enhance shared decision-making and increase patient and clinician adoption of safe and effective mHealth apps.

The objective of this study was to investigate patient and clinician attitudes about mHealth apps and to identify factors that may influence clinicians' willingness to recommend and patients' willingness to use mHealth apps. For this study, conversations about mHealth apps were grounded by discussion of a specific mHealth app being evaluated in an ongoing randomized controlled trial (RCT). The ability to examine these questions during the deployment of an existing mHealth app—rather than a theoretical tool—provided us with a unique opportunity to generate novel insights.

Methods

Qualitative Research Approach and Paradigm

The study team included clinicians (CAJ, MPD, and BKN), individuals with expertise in qualitative methods (SLK), implementation science (SLK), health services research (BKN, SLK, and JDP), and digital health technologies (DHT) (CAJ, BKN, MPD, and JDP). All members of the study team were employed by the University of Michigan (U-M), a large midwestern public university (CAJ, SLK, MPD, JDP, BKN) or a Veteran's Health Administration hospital (SLK, JDP). Given the qualitative nature of this study and the aim of understanding

XSL•FO
RenderX

participants' subjective experiences, a constructivist research approach was used.

Study Design and Setting

We used a descriptive qualitative study design to examine patient and clinician experiences with mHealth apps [46]. The study occurred at U-M from September 2023 to August 2024. The study adhered to the standards for reporting qualitative research reporting guidelines [47].

Participants and Sample

Patients

LowSalt4Life is a mHealth app designed to decrease dietary sodium intake in patients with hypertension. The app uses geofencing and reinforcement learning technology to deliver personalized, contextual push notifications about salt intake when patients are in grocery stores and restaurants. A pilot RCT (LowSalt4Life-1—NCT03099343) showed that contextual just-in-time notifications from the LowSalt4Life app resulted in greater reduction in dietary sodium intake in adults with hypertension compared to a control group (no app) over an 8-week period [48].

Purposive sampling methods were used to recruit patients from a cohort that participated in the LowSalt4Life-2 RCT (NCT05396001), which included 200 patients in the experimental arm (received personalized LowSalt4Life app) and 200 patients in the control arm [49]. Participants randomized to use the personalized LowSalt4Life app were invited via email to participate in a semistructured interview after exiting the LowSalt4Life-2 study.

Clinicians

Purposive sampling was used to recruit clinicians who provide direct care to patients with hypertension, including dietitians, pharmacists, primary care physicians, nephrologists, and cardiologists. Clinicians were contacted via the closed, moderated U-M Division of General Medicine email listserv or through targeted, direct emails to inquire about interest in participating in the study. Additionally, snowball sampling, in which interviewees were asked to identify colleagues who could provide valuable insights into the study, was used to recruit additional clinicians. These clinicians were also emailed invitations to participate in the study.

The clinician interviews preceded the patient interviews because patients were sampled from the LowSalt4Life-2 study and completion of the study was required before patients were approached for an interview.

Data Collection

The interview guides were developed using constructs from the technology acceptance model (TAM) [50,51], the unified theory of acceptance and use of technology (UTAUT) [52,53], the theoretical domains framework [54], and the technology integration model (TIM) [55].

The patient interview guide included two domains: (1) technical and material factors and (2) social and personal factors (Multimedia Appendix 1). The clinician interview guide included three domains: (1) technical and material factors, (2) social and personal factors, and (3) policy and organizational factors (Multimedia Appendix 1). The technical and material factors domain included constructs such as perceived usefulness and perceived ease of use. Constructs in the social and personal factors domain included attitudes, self-efficacy, identity, and social influence. Finally, workflow, training, and education were the constructs included in the policy and organizational factors domain.

The patient guide included 19 questions (plus probing questions), and the clinician guide included 14 questions (plus probing questions) (supplement). Both interview guides were iteratively updated as new information was encountered during interviews, and the final guides were approved by members of the study team (CAJ, SLK, BKN, JDP, and MPD).

The interviews were conducted either virtually via the Zoom platform or by phone by a clinician (CAJ) and a nonclinician research associate (SY). Prior to interviews, clinicians viewed a brief presentation about the LowSalt4Life app to (1) facilitate a shared understanding of the general capabilities of mHealth apps, (2) evaluate their attitudes about the LowSalt4Life app, and (3) have a common reference app to allow comparison of clinician and patient attitudes about mHealth apps in general. Each interview was audio recorded and transcribed.

Data Analysis

We conducted a deductive content analysis [56-58] using a rapid qualitative analysis approach to identify subcategories and categories within the domains of the theoretical frameworks. Rapid qualitative analysis is a particularly useful method when the data collection is targeted (eg, selection of interviewees) and processes (interview protocol) are highly structured [59-61]. The rapid qualitative analysis approach allowed us to maintain rigor while also working within the constraints of another study. Rapid qualitative analysis involves three analytic steps: (1) summarization of individual transcripts, (2) consolidation of transcript summaries by participant type (eg, patient or clinician), and (3) in-depth analysis [62].

Two study team members (CAJ, SLK) developed a summary template based on the domains in the interview guide, then independently reviewed, summarized, and discussed 3 interview transcripts to test and refine the template and summarization process. Thereafter, concurrent with ongoing data collection, each interview transcript was reviewed in detail, and transcript summaries that organized the data into the relevant domains were generated by the first author (CAJ). Data from the transcript summaries were transferred to patient or clinician data matrices to allow visualization of the data across domains, constructs, and participants. A detailed review of the data matrices by several study team members (CAJ, SLK, SY) led to the identification of patient and clinician subcategories within each domain. Through triangulation, the subcategories were then aligned to create broader categories by placing the patient and clinician data in a table that allowed comparison across domains and constructs (). CAJ and SLK met biweekly to discuss the data and resolve any discrepancies. The categories were finalized during meetings with members of the research team (CAJ, SLK, SY, JDP, and BKN).

XSL•FO
RenderX

Ethical Considerations

The study protocol (HUM00238747) was approved by the U-M Institutional Review Board. All participants provided written informed consent. All the study data was deidentified and stored in a Health Insurance Portability and Accountability Act–compliant, U-M–approved electronic database to ensure privacy and confidentiality of participants. Patients received a US $25 gift card after completing the interview. Clinicians did not receive an incentive for participating in the study.

Results

Patient and Clinician Information

Prior to initiating the study, we planned to interview 20 clinicians and 20 patients. However, data saturation (no new analytical information identified by the research team) was reached after 20 clinician interviews and 28 patient interviews. Among the 20 clinicians interviewed, the mean number of years in practice was 17 (SD 11.6) years (Table 1) and most were general internists (n=12, 60%). The clinician interviews lasted between 22 to 49 minutes. The mean age of the 28 interviewed patients was 59 (SD 12.1) years, and 16 (57.1%) patients were female (Table 1). Two (7.1%) patients self-identified as Asian, 4 (14.2%) self-identified as Black/African American, 21 (75%) self-identified as White, 1 (3.6%) self-identified as unknown, and none self-identified as Hispanic. The patient interviews lasted between 21 and 63 minutes.

Table . Patient and clinician demographic data.

Characteristics	Participants
Patients (n=28)	
Age (y), mean (SD)	59 (12.1)

[a]Race or ethnicity was self-reported.

[b]GED: general educational development.

Patient and clinician attitudes about mHealth apps fit within 1 of 7 categories related to the 3 theory-based domains (Table 2). Within the technical and material factors domain, the categories identified were apps as tools to improve health by extending

XSL•FO
RenderX

care, the role of apps in enhancing the patient–clinician relationship, and the need for simplicity and efficiency in app design. Categories in the social and personal factors domain included prior experience with mHealth apps, comfort with technology, and the influence of recommendations from trusted sources. Education and hands-on experience were the category identified in the policy and organizational factors domain. These categories are described in more detail below.

Table . Categories and subcategories related to patient and clinician attitudes about mHealth[a] apps.

Domain and category	Patient subcategory	Clinician subcategory
Technical and material factors		
Tools to improve health by extending care	mHealth apps are tools to improve health	mHealth apps can extend care beyond episodic visits
Enhancing the patient–clinician relationship	mHealth apps can improve patient–clinician engagement	mHealth apps can improve the patient–clinician relationship, if beneficial
Simplicity and efficiency	mHealth apps must be simple	Patients stop using mHealth apps that are complex or require a significant time commitment.
Social and personal factors		
Prior experience with mHealth apps	Positive experience with mHealth apps but concerns about data privacy	Personal use and prior recommendation of mHealth apps, but concerns about data privacy
Comfort with technology	Confident when using technology	Confident when using and discussing technology; older adults are not confident when using technology
Recommendations from trusted sources	Influence of trusted individuals	Influence of trusted organizations and colleagues
Policy and organizational factors		
Education and hands-on experience	Access to education about an mHealth app	Use of mHealth app prior to recommending

[a]mHealth: mobile health.

Technical and Material Factors

Tools to Improve Health by Extending Care

Both patients and clinicians described 1 of the benefits of mHealth apps as the capacity for use outside traditional health care settings. For patients, mHealth apps provide them with an always accessible tool to encourage healthier behaviors.

> *So, just that tool to have with you, you know an app on your phone. It's very helpful to be able to have that information with you.* [Patient 27, female, 55-year-old]

For clinicians, mHealth apps can reinforce their health-related recommendations outside of regularly scheduled clinic visits.

> *This is almost a way to extend my advice in a more practical way that allows them to be more aware and hopefully more compliant, or make better choices...* [Clinician 8; 19 years of experience]

Enhancing the Patient–Clinician Relationship

In general, patients and clinicians believed that mHealth apps could improve the patient–clinician relationship. Patients perceived that accurate, organized data from mHealth apps could improve their engagement with their health care, including providing additional information to facilitate meaningful conversations with clinicians and changes in management.

> *Yeah, I think it'd be terrific for my provider to be able to see the data...I think that that could be helpful to fuel a good conversation with a doctor.* [Patient 23, male, 57-year-old]

Clinicians suggested that equipping patients with a tool to support their health care would enhance their relationships with patients.

> *So, either way it would augment the physician-patient relationship. So even if it [patient data] does not feed to me, I think it would still allow me to give a patient a tool that can help them with their, with supporting their medical needs.* [Clinician 8; 19 years of experience]

While clinicians recognized the potential benefits of mHealth apps on the patient–clinician relationship, they expressed concerns about remembering available apps, a need for support from staff, and managing new data streams.

> *So, incorporation of this [mHealth app] into practice would involve others in the practice to assist. Either nurse practitioner or preferably a dietitian.* [Clinician 18; 44 years of experience]

> *On the clinician perspective, okay, now that you have all this extra data...Do you have the time to take a look at it. And then how do you actually turn that into changes in your management?* [Clinician 17; 8 years of experience]

Simplicity and Efficiency

Patients identified being easy to use and requiring a low time commitment as key considerations for the use of mHealth apps. In fact, they highlighted that complexity could be an important barrier.

XSL•FO
RenderX

> *Well, if it got too techy, I wouldn't have the patience... If it gets too technical, then no, it's not going to be useful or helpful to me.* [Patient 9, female, 86-year-old]

Additionally, clinicians expressed concerns about patients starting to use apps but eventually discontinuing use for reasons including complexity, too much of a time commitment, or too much manual data entry.

> *Have to keep an eye on the utilization. I think if they find it hard to use, they won't use it, or they might use it initially, but then fall off.* [Clinician 18; 44 years of experience]

> *If you're having the data, enter everything and it's not helping you along the way gets tiresome to patients. So, they usually use it for a while and give up.* [Clinician 16; 28 years of experience]

Social and Personal Factors

Prior Experience With mHealth Apps

Patients and clinicians both talked about positive experiences with mHealth apps. Many used apps for fitness tracking, weight loss, and sleep monitoring. For example:

> *I have apps that are really important to me, and one of them is my EKG app.* [Patient 3, female, 67-year-old]

> *I mean, I think I love mobile health applications. I mean, I have a ton of them on my phone for all kinds of different things.* [Clinician 9; 1 year of experience]

However, both patients and clinicians expressed concerns about data privacy, with some patients stating that they would be unwilling to use an mHealth app that tracked specific types of data (eg, location).

> *The part that I think would be almost a deal breaker for me is the like background location tracking, or like you have it on all the time...I just would have some like privacy concerns.* [Patient 16, male, 34-year-old]

> *And so, you know, some folks will probably have a hard time with the kind of knowledge that they are quote unquote being tracked.* [Clinician 17; 8 years of experience]

Comfort With Technology

Confidence and comfort with using technology were common considerations in the use of mHealth apps for both patients and clinicians. Patients, for the most part, expressed confidence when using various types of technology and generally described themselves as tech-savvy. Older patients noted that technologies should be designed to facilitate use by older adults and expressed a willingness to learn to use health technologies if necessary.

> *I am the type where if there is a need to use an app, especially for healthcare I would learn to use the app.* [Patient 8, male, 72-year-old]

> *There are some things that I can do on a computer, some things that I can do on my tablet. And if I learn to do something, I pretty much know it.* [Patient 9, female, 86-year-old]

Clinicians also described being open to new technologies and viewed themselves as tech-savvy. In addition, they expressed confidence when discussing technologies with patients.

> *Yeah, as long as I've had some time to work with it, I can. You know I'm reasonably confident. But I'm not. I don't have a phobia of technology. I am open to it.* [Clinician 18; 44 years of experience]

On the other hand, clinicians generally did not view patients as tech-savvy, and they specifically expressed concerns related to older adults' interest and ability to effectively use mHealth apps and other technologies.

> *I have some patients where I could probably tell you right off the bat. They're not gonna be interested, just cause they're not into tech type things, you know. I have some patients that still, you know, wish they could have their flip phone. And you know, some of the old school stuff or you know, patients that just prefer to stay off their phones altogether if they can. Usually, it's my older generation of patients, although sometimes they surprise you.* [Clinician 3; 10 years of experience]

Recommendations From Trusted Sources

Trusted sources were an important factor identified by both patients and clinicians related to their willingness to use or recommend mHealth apps. A recommendation from health care providers, friends, or family members would influence patients' decisions to use an app.

> *And my doctor, if she said, I want you to try this application because I think it's gonna make an improvement of your health, then I would do it.* [Patient 7, female, 62-year-old]

Guideline recommendations from professional societies or organizations would influence clinicians' decisions to recommend an app to their patients. Additionally, some clinicians stated that if their colleagues were recommending an app to their patients, or if a respected colleague recommended an app, they would be more inclined to recommend the app to their own patients.

> *I mean, I do think something like, you know, a major guideline recommendation would be at least something, particularly if you know I'm reading the recommendation, and I see there is something behind it. Potentially like a provider that I like, or trust would be useful too.* [Clinician 1; 15 years of experience]

Policy and Organizational Factors

Education and Hands-on Experience

Another facilitating factor for use of mHealth apps was gaining familiarity with an app. Specifically, patients were interested in readily available educational resources or assistance to increase their comfort with an app and to troubleshoot any problems that arise.

XSL•FO
RenderX

> *Maybe like something where you could have a chat session with somebody to help you get the answer you need.* [Patient 4, male, 57-year-old]

Most clinicians preferred to personally use an app prior to recommending it to patients. Additionally, many clinicians described recommending mHealth apps that they had personally used.

> *I think just seeing the like interfaces on the app, seeing what the patient sees is huge for me. I don't like to like throw them blind into something.* [Clinician 4; 2 years of experience]

Discussion

Principle Findings

mHealth apps are an increasingly important part of the health care landscape and can enhance patients' autonomy and engagement with their health care. Our findings show that overall, patients and clinicians have positive attitudes about mHealth apps, including their potential usefulness in extending care outside of traditional health care settings and enhancing the patient–clinician relationship. Patients and clinicians identified several common factors to facilitate the recommendation or adoption of mHealth apps. These factors included the importance of the ease of use of an app, receiving recommendations about mHealth apps from trusted sources, and access to education about or hands-on experience with mHealth apps. Prior experience with mHealth apps and comfort using technology were also described as facilitating factors by both patients and clinicians.

Other studies have indicated that both patients and clinicians have concerns about mHealth apps eroding the patient–clinician relationship and therapeutic alliances because of less face-to-face interaction [63]. This concern is well-founded as the introduction of technology can lead to a form of automation bias in which clinicians over-rely on mHealth apps and their outputs, or inappropriate delegation of tasks to mHealth apps [64]. Clinicians will need to exercise vigilance and make nuanced decisions about the appropriateness of mHealth apps for a given task to both ensure safety and that the patient–clinician relationship remains intact. Further, measures to avoid patient overreliance on mHealth apps will need to be in place because this could also negatively impact the patient–clinician relationship [65]. In a study by Preiser and colleagues [66], general practitioners in Germany noted that a symptom checker app could result in decreased unnecessary office visits and decreased clinician workload. However, the clinicians preferred that patients err on the side of caution and seek their help early to circumvent avoidable suffering. Ultimately, technology and safe, humane care should not be treated as mutually exclusive. Consistent with the TIM [55], this will require further exploration of how mHealth apps can extend patient and clinician capabilities, and both patients and clinicians acknowledging the strengths and limitations of technology and one another [67].

While mass media campaigns [68] and direct-to-consumer marketing [69] have proven effective at influencing patient health decisions, patients in our study noted that their attitudes about an app would be most influenced by trusted individuals (eg, friends, family, and health care providers). Therefore, clinicians must actively engage with patients and their family, friends, and caregivers to encourage the adoption and sustained use of safe and effective mHealth apps [70]. Further, studies have shown that patients' adoption of health-promoting behaviors may be influenced by individuals in nontraditional health care settings. For example, in an RCT by Victor and colleagues [71], Black male patients with uncontrolled hypertension were assigned to either an intervention group in which barbers at Black-owned barbershops encouraged meetings in barbershops with specialty-trained pharmacists who prescribed antihypertensive medication, or to a control group in which the barbers encouraged lifestyle modifications and doctor appointments. While both groups experienced improvement in their blood pressure at 6 months, the improvement was much greater in the group that met with the pharmacists and were prescribed antihypertensives. This study highlights both the benefits of treating patients in their natural environments and the benefits of leveraging the influence of trusted members of the community to promote healthy behaviors. Partnerships such as this should be explored to promote the adoption and sustained use of mHealth apps that have proven safe and effective.

Clinicians in our study noted that trusted colleagues, specialty organizations, and evidence-based guidelines, each of which may be related to the subjective norms described by UTAUT, would strongly influence their decision to recommend an app to a patient. However, clinicians did not describe app certification or approval by a regulatory agency (eg, Food and Drug Administration [FDA]) as necessary for recommending an app to a patient. In other studies, clinicians have identified a lack of certification as a barrier to recommending mHealth apps. For instance, in a study by Schroeder et al [36], clinicians expressed that they view mHealth apps similarly to other medical products and that apps should be given an official certification to ensure more trust. This study was conducted in Germany, which in 2020 became the first country in the world to approve certain mHealth apps for prescription and coverage by health insurers [26]. Additionally, Germany maintains a directory of approved mHealth apps managed by the German Federal Institute for Drugs and Medical Devices known as Digitale Gesundheitsanwendungen. As of July 2024, there were 56 mHealth apps listed by the German Federal Institute for Drugs and Medical Devices, and over 274,377 prescriptions were recorded from 2020 - 2023, with Zanadio (Sidekick Health Germany), a weight loss app, prescribed most frequently during that period [72]. Another study based in the United Kingdom showed that clinicians believed the most important factor encouraging mHealth app prescription was if it had a National Health Service stamp of approval [32]. The US FDA plays a role in the regulation of mHealth apps [43] but the vast majority of mHealth apps are not regulated by the FDA. While it may not be feasible for the FDA to rigorously evaluate every app, attention should be given to developing interventions that facilitate clinician confidence in the safety and efficacy of evidence-based mHealth apps as studies have shown that many

XSL•FO
RenderX

apps in app stores with high ratings often have low usability or clinical usefulness [73].

Our study showed that patients and clinicians have differing beliefs about patients' level of tech savviness. While most patients reported using mHealth apps, clinicians generally believed that older adults would not be interested, or they would be unable to effectively use mHealth apps [63]. A recent study showed that over 81% of older adults use DHTs, and over 40% reported any use of mHealth apps [74]. Our findings suggest that clinician bias could be a barrier to recommending mHealth apps to those who may benefit most (eg, older adults). During the COVID-19 pandemic, the use of DHTs significantly increased across all age groups. However, disparities widened with older adults significantly less likely to use DHTs compared to younger adults [75]. Still, older adults' increased use of DHTs during the COVID-19 pandemic suggests that they are interested and capable of using mHealth apps, but prior to the pandemic, they were not using them for various reasons that should be explored. Moreover, views expressed by older adults in our study are consistent with this as a 72-year-old patient stated: "I am the type where if there is a need to use an app, especially for healthcare I would learn to use the app." Older adults are likely to have a greater burden of chronic disease [11] and impairments (eg, physical and cognitive) that can limit their ability to use DHTs, and this should be considered when recommending mHealth apps to patients. The results from our study suggest that clinicians should take an individualized approach to recommending mHealth apps to older adults. Notably, age moderates the constructs in the UTAUT framework (eg, performance expectancy, effort expectancy, social influence, and facilitating conditions) that predict behavior intention to use technologies [52,53]. When studying older adults' use of mHealth apps, using a framework that does not include age, but does include variables associated with the aging process (eg, memory or physical limitations) may add more nuance and avoid introducing age-related bias. Further, interventions are needed to both address clinician bias [76] and to encourage patients and their families or caregivers to advocate for themselves.

Clinicians also noted barriers to recommending mHealth apps that included getting patients oriented, time constraints, a need for support from staff, and a lack of optimized workflows to facilitate review and use of data generated by mHealth apps, which highlights the importance of the environment and situational context described in the TIM [55]. These concerns must be weighed against the benefits to patients. For instance, patient-generated data has been shown to increase patient health literacy and to help patients better engage with their health providers [77,78]. User-centered mHealth apps also have the potential to increase adherence by providing individualized, just-in-time reminders and advice during vulnerable times outside of clinics and hospitals as demonstrated in conditions such as human immunodeficiency virus and congestive heart failure [79-81]. Like other studies, clinicians in our study expressed interest in having data from mHealth apps integrated into electronic health records (EHR) for efficient visualization, analysis, and application. This type of integration would require policy and organization-level interventions that support the flow of new data streams, interoperability between systems, and application of data from mHealth apps to improve patient–clinician engagement and health outcomes. Furthermore, health care organizations and app developers would need to partner with EHR vendors to ensure that their products are interoperable, allowing seamless data exchange between the EHR and mHealth apps. Collaborations between patients, clinicians, health system leaders, and developers will be necessary to ensure that apps address relevant clinical problems, are easy to use, and simple to set up. Thus, user-centered design principles addressing the patient, caregiver, and clinician perspectives must be used to facilitate recommendation by clinicians and adoption by patients.

James et al [82] described the "4E's (ease, evidence, experience and expectations)" that inform the mindlines influencing clinicians' decisions to recommend mHealth apps. Mindlines are collectively reinforced, internalized tacit guidelines, which are informed by brief reading, but mainly (by) clinicians' interactions with each other (as well as) opinion leaders, patients, and pharmaceutical representatives and by other sources of largely tacit knowledge that build on their early training and their own and their colleagues' experiences [83]. Our study reinforces the potential influence of the 4E's described by James and raises the question of whether the mindlines concept and the 4E's informing them could be expanded to patients. However, it should be noted that a category related to expectations did not emerge in our study, which could be due to the theoretical frameworks used and the constructs used. Therefore, the role of patients' and clinicians' expectations around mHealth apps should be explored.

Limitations

Strengths of this study include using an mHealth app that was being actively studied and deployed as a common frame of reference for discussions about mHealth apps with patients and clinicians. Additionally, we combined constructs from well-established technology adoption (eg, TAM and UTAUT), and implementation science (eg, theoretical domains framework and TIM) frameworks to account for limitations of each framework, which allowed us to identify facilitators and barriers that could inform development of interventions to increase recommendation and adoption of mHealth apps by patients and clinicians.

This study also had key limitations. First, it occurred at a single academic health center in a metropolitan area. There are known geographic differences in smartphone, internet, and DHT use, with lower rates of access among patients in rural areas. Second, our study only included patients enrolled in the LowSalt4Life-2 study, a study of a single mHealth app. Hence, the results may be affected by selection bias as participants may have had a favorable view of mHealth apps and interest as indicated by their participation in the study. Third, the qualitative design of our study does not allow us to infer that the attitudes expressed by participants in our study are shared by others. Fourth, because we used a deductive analytic approach that included domains from established frameworks, we may not have identified additional relevant or novel attitudes that may have been discovered with an inductive approach. Finally, we cannot

XSL•FO
RenderX

conclude that addressing the identified patient and clinician attitudes will result in increased recommendation or adoption of mHealth apps. Our study did not measure intention to use, behavior intention, use behavior, or technology use, which are downstream constructs in the TAM, UTAUT, and TIM frameworks, respectively [50-53,55]. Thus, studies are needed to determine the impact of interventions that address the identified attitudes on patient adoption and clinician recommendation of mHealth apps.

Conclusions

In this qualitative study, patients and clinicians generally had a positive view of the potential benefits of mHealth apps. Both groups also identified several similar factors that facilitate the use of mHealth apps. However, overall, patients' and clinicians' views about older patients' interest in and ability to use technology differed. As mHealth apps are developed and implemented, careful consideration must be given to both patients' and clinicians' attitudes and agreement and disagreement between these key stakeholders. This approach will allow the development of implementation interventions that facilitate recommendation of mHealth apps by clinicians and adoption of mHealth apps by patients.

Abstract

Background: In the current digital landscape, ensuring optimal usability is one of the most crucial factors determining the success of any mobile app. Questionnaire-based usability evaluations represent a highly prevalent methodology for this purpose. To date, questionnaires have been developed to assess the general system usability; however, there are hardly any questionnaires specifically designed to assess the usability of mobile health (mHealth) apps. The most widespread, the mHealth App Usability Questionnaire (MAUQ), has been developed in 4 versions according to the type of app (interactive or standalone) and the target user (patient or provider).

Objective: The objective of this study was to translate and validate the English version of the MAUQ (standalone, for patients) into a Spanish version (S-MAUQ).

Methods: The methodology used here follows that proposed by Sousa and Rojjanasrirat, which comprises 4 stages. The initial stage of the process entails a translation, harmonization, and adaptation procedure. The second and third entailed content validation (by 10 experts) and face validation (by 12 target users), respectively, which were conducted to evaluate the relevance and clarity of the questionnaire items. The item-level content validity index, scale content validity index (S-CVI), item-level face validity index, and scale face validity index (S-FVI), as well as the modified kappa statistic (κ) were used to evaluate interrater agreement among the raters, considering the probability of agreement by chance (Pc). The fourth and final stage of the process involved the assessment of the questionnaire's reliability. A sample of 61 young adult participants installed an mHealth app (the Yazio app), used it, and responded to the S-MAUQ. The Cronbach α value for the entire questionnaire and its subscales were then calculated.

Results: For the second stage, the S-CVI was initially 0.778. We removed items #14 and #15 from the Spanish version as they were unclear and not relevant. The S-CVI changed to 0.881. The third stage had an S-FVI of 0.927, indicating that the items are clear and straightforward for the nonexpert target user to understand. Furthermore, with each κ value >0.74, the validity of the instrument is supported. The fourth stage demonstrated the reliability of the S-MAUQ with a Cronbach α value of 0.87.

Conclusions: The final version of the S-MAUQ met the validation criteria, demonstrating reliability and validity that are comparable with those of the original version. Consequently, the S-MAUQ is suitable for evaluating the usability of mHealth apps for young Spanish adults. Further research involving larger and more diverse samples is recommended.

Introduction

mHealth is an acronym for mobile health, which is used to describe the practice of medicine and public health that is supported by mobile devices [1]. Such mobile devices encompass mobile phones, tablets, and wearable devices, including smart watches. mHealth apps can collect health information for practitioners, researchers, and patients alike and can monitor patients' vital signs in real time. They facilitate direct care using mobile telemedicine and are used in the training of and collaboration with health workers [2].

The use of mHealth apps is increasing at a considerable rate [3], as evidenced by the growing number of users or patients [4]. Moreover, the emergence of innovative eHealth and

XSL•FO
RenderX

mHealth technologies has the potential to significantly improve the cost-effectiveness of the health care system [5].

Presently, these health apps are typically developed either by researchers or, in the majority of cases, by commercial companies, without collaboration between these two groups. The lack of interaction between researchers and commercial developers in the field of health-related apps has resulted in a situation where commercially available apps have not been subjected to scientific validation and apps that have been developed from research projects are not commercially available [6].

It is imperative that mHealth apps are designed in a manner that ensures optimal *usability*. Such apps must be straightforward to use and capable of achieving their intended objectives in an efficient manner. Well-designed mHealth apps have demonstrated cost-effectiveness through the education and empowerment of patients as well as through improved treatment adherence. However, some reviews have highlighted the absence of criteria for assessing the validity of mHealth apps.

mHealth apps can be classified into two principal categories: those designed for patients and those designed for health care providers. *Patient-focused* apps are designed to assist with the management of health behaviors, whereas those oriented toward *health care providers* facilitate services such as prescriptions and education. Furthermore, mHealth apps can be classified into two additional categories: *interactive* apps, which facilitate communication with health care providers, and *standalone* apps, which include features such as reminders but lack provider interaction [7].

The optimal *usability* of apps is characterized by several key attributes, including efficiency, satisfaction, learnability, memorability, and low error rates [7,8]. However, the intrinsic constraints of mobile devices, notably their limited display area, can present obstacles to the attainment of these objectives [9].

The People at the Center of Mobile App usability model considers the user, task, and context of use to evaluate usability. This includes the cognitive load associated with tasks such as exercising while using the app, as discussed by Harrison et al [10]. To minimize errors, usability should be assessed using the following criteria: effectiveness, efficiency, satisfaction, learnability, memorability, and cognitive load [10].

A few usability scales have been evaluation to ascertain their relative importance in the context of the development of general software systems and mobile apps. For example, the Mobile App Rating Scale (MARS) [11], its user version (uMARS) [12], System Usability Scale [13,14], and Post-Study System Usability Questionnaire [15]. However, these scales are not appropriate for evaluating mHealth apps, as they were not developed with mHealth apps as a specific focus.

One of the most pivotal usability scales for assessing the usability of mHealth apps is the mHealth App Usability Questionnaire (MAUQ) [7]. This assesses the ease of use, interface, satisfaction, and usefulness of mHealth apps for end users.

The standalone for patient version of MAUQ has been translated, among other languages, into Malay, German, and Italian [16-18]. It is noteworthy that, while this research was being developed, another related study was published (a Spanish version of MAUQ standalone, for patient [19]) but adapted to breastfeeding support apps. However, it has too many differences from the original and some incorrect formulas, as will be addressed in the discussion section.

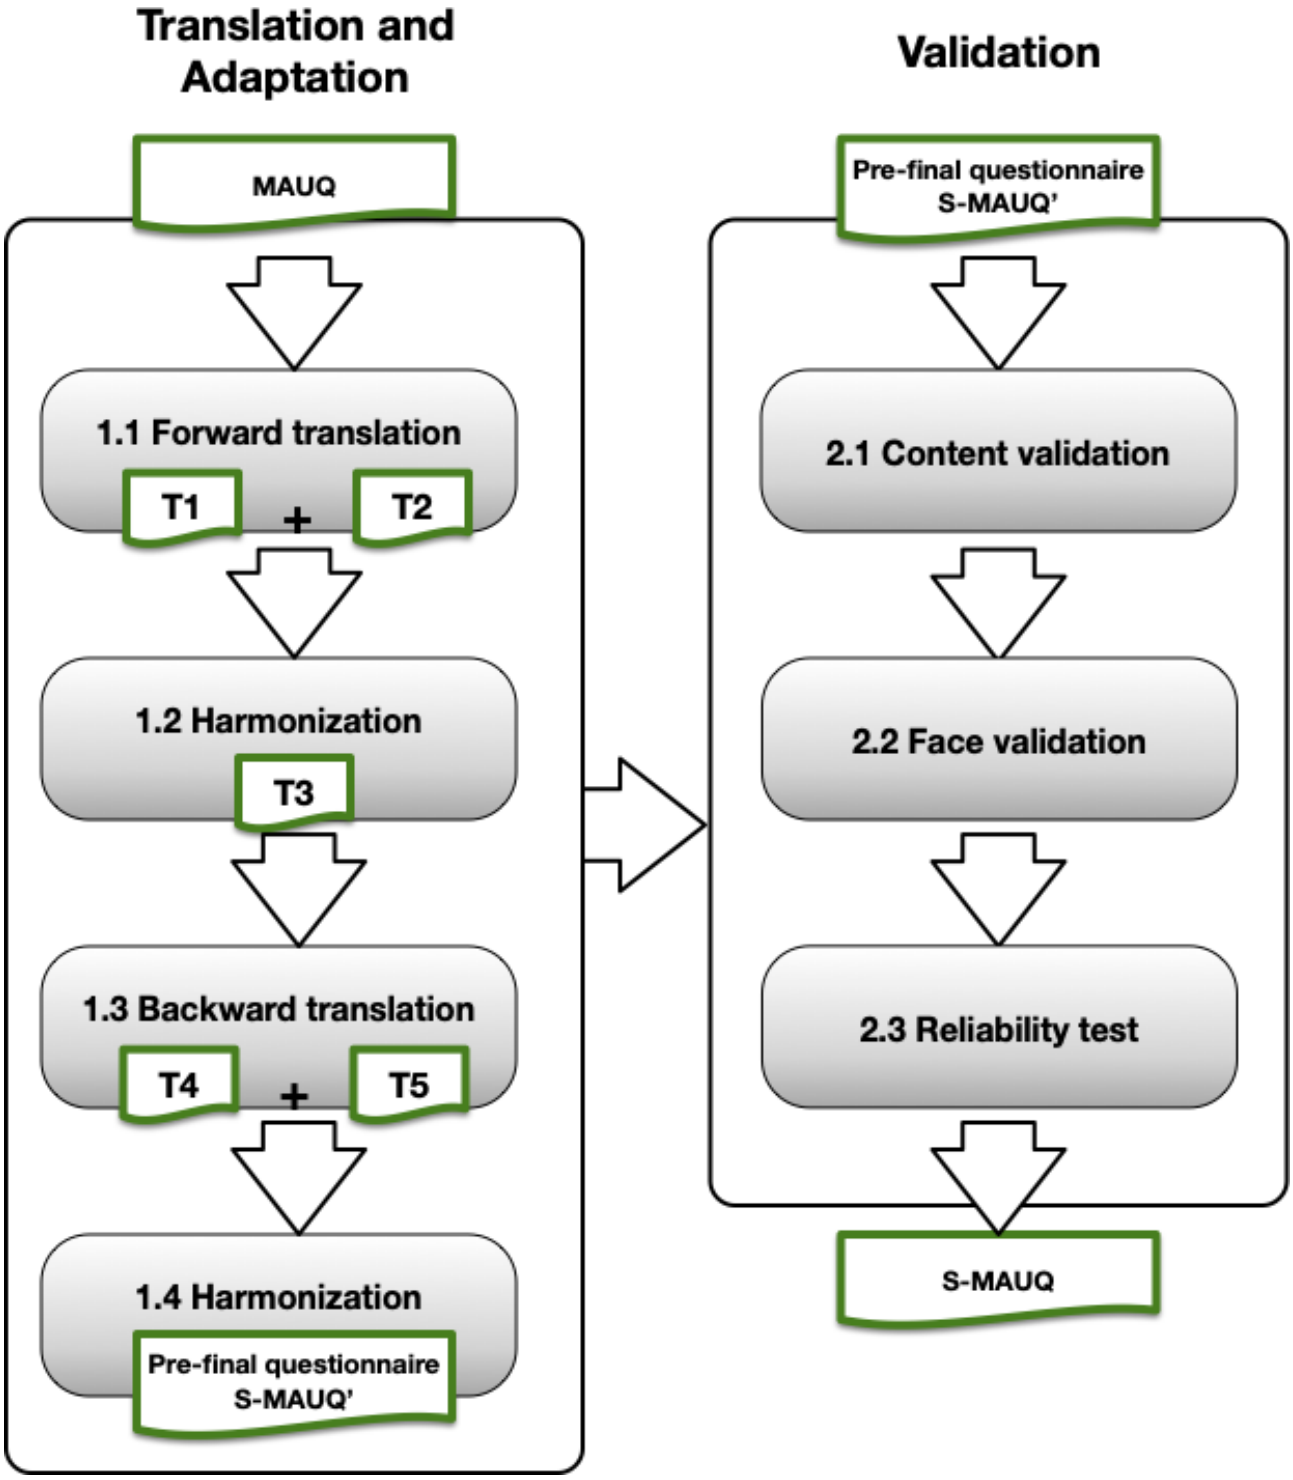
The objective of our study was to translate and validate the English version of the MAUQ (standalone, for patients) into a Spanish version (S-MAUQ) for use in future mHealth app research and development.

The importance of the translation into Spanish and its corresponding validation lies in two fundamental points: on the one hand, the large size of the Spanish-speaking community and, on the other, the cultural diversity of the type of user of these apps. Without this linguistic adaptation, these questionnaires would be out of reach for many users.

Methods

Overview of the Questionnaire

As previously stated, the MAUQ, developed and validated by Zhou and colleagues [7], is designed to assess the usability of mHealth apps among patients and health care providers. There are two versions of MAUQ, one for interactive apps and one for stand-alone apps. Each also addresses two of its potential users: patient or health care professional. We will work on MAUQ for standalone apps intended for patients. Always consider that the term “patient” refers to a person who uses an mHealth app to manage their health either for maintenance or improvement.



The questionnaire is comprised of 3 subscales or dimensions: ease of use (items #1 to #5), interface and satisfaction (items #6 to #12), and usefulness (items #13 to #18). Participants are required to indicate their level of agreement with each item on a 7-point Likert scale, with 1 representing strong disagreement and 7 representing strong agreement. The overall usability of the app is determined by calculating the total score and the mean score of all statements. A higher overall mean score is indicative of superior app usability. Conversely, a mean score <4 indicates suboptimal usability.

The original MAUQ (standalone, for patient version) exhibited robust internal consistency, with an overall Cronbach α value of 0.914. This indicates a high degree of correlation between the questionnaire items, indicating good reliability. The study was conducted in 2020 [7].

The methodology used to translate and validate the original MAUQ (standalone, for patient version) into Spanish followed the approach proposed by Sousa and Rojjanasrirat [20], with the objective of ensuring equivalence between the original and translated versions. The process is comprised of several steps (illustrated in Figure 1), which can be grouped into the following 4 stages: translation and adaptation, content validation, face validation, and internal consistency reliability.

XSL•FO
RenderX

Figure 1. The flow of translation, cross-cultural adaptation, and validation process for the Spanish version of the mHealth App Usability Questionnaire (S-MAUQ).

Translation and Adaptation Process

The preliminary phase of the translation process entailed the participation of two certified translators, each with a specialized understanding of both Spanish culture and linguistics. These professionals engaged in a forward translation from English to Spanish. One translator had a background in computer science, while the other had a background in health sciences. This resulted in the generation of two distinct documents designated T1 and T2.

Subsequently, the documents (T1 and T2) underwent a harmonization process. A third translator, a Spanish language teacher with more than 5 years of teaching experience, was tasked with identifying any ambiguities; discrepancies; and differences in words, sentences, grammar, and meaning. This was accomplished through a comparison of T1 and T2 with the original MAUQ. Any discrepancies and ambiguities were discussed and resolved through a process of consensus decision-making involving the third translator, the first two translators, and two members of the research team. The process

XSL•FO
RenderX

culminated in the production of an initial translated version of the MAUQ document (T3).

In the third phase of the process, the translated version of the MAUQ (T3) was provided to 2 independent native Spanish speakers who had acquired English as a second language. One individual (a computer science lecturer) was a content expert in the instrument's construct, while the other had no prior knowledge of the instrument (an English language teacher). The 2 participants then produced independent back-translated versions of the MAUQ (T4 and T5).

Last, a committee was established comprising 3 researchers, the translators involved in the initial and concluding stages, and the original developers of the MAUQ (when necessary). The committee conducted a comparative analysis of the documents with the original MAUQ, engaging in discussions via email and web-based meetings. Any ambiguities or inconsistencies in cultural meaning and expression of words and sentences and the format of the answers were addressed and resolved through consensus among the committee members. This process resulted in the development of the prefinal Spanish questionnaire, designated as S-MAUQ'.

Content Validation and Face Validation

Content validation is achieved by a panel of experts who assess the relevance and clarity of questionnaire items for measuring the usability of health-related mobile apps. Face validation is accomplished by a set of nonexperts or target users who specifically assess the clarity of the items.

Participants

For the content validation, a panel of 10 experts was formed. Our panel included 3 mobile app developers, 2 senior lecturers with a PhD in computer science, 2 usability experts, and 3 PhD senior lecturers and health-related practitioners.

For the face validation, 12 nonexpert participants were involved.

Recruitment

For the content validation, the 10 expert participants were carefully selected in order to adequately cover all areas of expertise involved. After being informed of the study's objective, all participants signed the corresponding informed consent form.

For the face validation, users were randomly selected from an openly chosen sample. The inclusion criteria were as follows: (1) native Spanish speaker, (2) older than 18 years, and (3) familiar with smartphones. The exclusion criteria were being (1) health-related practitioners, (2) mobile app developers, or (3) computer science students or professionals.

Participants were asked to complete an anonymous web form that included the informed consent, gender, date of birth, and level of education.

Setting

The group of expert participants completed their evaluations remotely and sent them to us via email. The nonexpert participants completed their evaluation online via an anonymous web form.

Study Procedures

In the content validation stage, each expert is required to assign a score on a scale of 1 to 5 to each item. A score of 1 indicates that the item was not relevant or clear, while a score of 5 indicates that the item was highly relevant and clear. Subsequently, scores of 1 to 3 were recategorized as 0, indicating irrelevance or unclarity, while scores of 4 and 5 were recategorized as 1, indicating relevance or clarity. The final categorization was conducted with the objective of obtaining dichotomous values. In numerous other studies, the range extends from 1 to 4. In contrast, in our study, the range was from 1 to 5. However, the current quality standards are more demanding, as a rating of 3 was considered unsatisfactory. In addition, there were 3 instances of unsatisfactory performance, as opposed to only 2 instances of acceptable performance.

On the other hand, in the face validation, which was less demanding with the nonexpert evaluators, the scores ranged from 1 (indicating that the item was not understandable) to 4 (indicating that the item was very understandable). Scores of 1 and 2 were recategorized as 0 (not understandable), and scores of 3 and 4 were recategorized as 1 (understandable). This was less demanding because the chosen scores were taken directly without considering the middle 3 negative values as we did with the experts.

The calculations for the 2 types of evaluation were as described in the following statements.

If we have N as the number of raters or evaluators; A_C as the number of expert raters who concur that the items are relevant, unambiguous, and intelligible; and A_F as the number of nonexpert raters who concur that the items are clear and comprehensible, the item-level content validity index (I-CVI) and the item-level face validity index (I-FVI) were calculated by dividing the propoortion of raters who agreed that an item was clear and relevant to the domain by the total number of raters.

In conclusion, it can be proposed that:

I−CVI=ACN and I−FVI=AFN

Items with an I-CVI or I-FVI of at least 0.79 were relevant, unambiguous, and understandable to the target users, indicating their potential inclusion in the questionnaire [21,22].

The scale content validity index (S-CVI) and scale face validity index (S-FVI) can be calculated as the means of the corresponding I-CVI and I-FVI. This is accomplished by dividing the sum of each item by the total number of items [23].

Moreover, it is essential to determine the level of agreement among the 10 experts. This can be accomplished by calculating the modified kappa statistic [21,24,25], which can be expressed as follows:

κCVI=I-CVI−Pc1−Pc and κFVI=I-FVI−Pc1−Pc

In this formula, P_C represents the probability of chance occurrence. The initial determination of the probability of agreement by chance for each item was determined using the

XSL•FO
RenderX

following formula (the formula for a binomial random variable) [21]:

Pc=(NA)·0.5N=N!A! (N−A)!·0.5N

This equation has its origins in the field of probability theory, specifically in the binomial distribution. The probability of obtaining precisely *A* successes in *N* independent Bernoulli trials (with the same rate *p*, in this case *1/2*) is given by the probability mass function (or discrete probability density function):

Pc=(NA) pk(1−p)N−A and for p=1/2 → Pc=(NA) 0.5N

Graphically, the interpretation criteria for the modified kappa statistic, as outlined by Wynd et al [26] and Cicchetti and Sparrow [27], is shown in Figure 2.

Figure 2. Interpretation criteria for the modified kappa statistic.

Reliability (Internal Consistency) Validation

Participants

For the internal consistency validation, the participants were selected from among students enrolled in the School of Engineering at the University of Malaga and the Campus of International Excellence (Andalucía Tech). The required sample size was calculated as 38 participants for the purposes of reliability testing, with an expected Cronbach α of 0.80 and an expected precision of 0.1 at 95% CI [28]. Given the projected rate of nonparticipation of 20%, the final sample size was determined to be 48.

Recruitment

Participants were recruited through direct invitations from the involved professors during class time. Those who agreed to take part in the study were required to complete a web-based informed consent form. Inclusion criteria were an absence of any known medical illness and ownership of a smartphone.

Setting

Participants performed the tasks on their smartphones and in their own classrooms and used a Google Form to submit their answers to the S-MAUQ.

Study Procedures

Participants were instructed to install the Yazio app on their mobile phones. Yazio, a standalone mHealth app for patients, was selected for the usability study due to its popularity. It is one of the most widely used nutrition apps in the world, helping people lead healthier lives globally. Its availability on both Android and iPhone devices [29,30] combined with its similarity to MyFitnessPal—an app frequently used in previous studies but that requires additional resources to be used—made it a suitable choice. A concise overview of the Yazio app, along with the essential steps for preliminary configuration, was displayed on the classroom projector. This procedure should be carried out exclusively at the point of the initial execution of the app following its installation.

Subsequently, participants were required to undertake the tasks detailed in Textbox 1.

XSL•FO
RenderX

Textbox 1. Sheet of tasks to be performed using the Yazio app.

1. Create initial profile when running the app for the first time (take a screenshot of the screen that appears at the end of the process, after discarding the tutorial)
2. Use the functions available in the Daily and/or Profile menu to add records or data for today:
   a. Add the following foods consumed during breakfast
      - 1 black coffee
      - 2 slices of bread (bimbo) without crust
      - Natural orange juice, 200 mL
      - Olive oil, 1 tablespoon
      - Product with barcode 8410095040362 (or scan it from the product code photo)

   b. Modify (in the profile) daily water amount goal: 2.5 liters
   c. Add water consumed: 1.75 liters
   d. Add activities (exercise completed) by pressing "More"
      - "walk, general" 30 minutes
      - "fast walk (6 km/h)" 10 minutes

   e. Add 2 notes or indications about how your day is going
      - "I slept well"
      - "bored"

   f. (Finally, take the necessary screenshots, 2 or 3, to collect the data entered)
3. Identify and note (via screenshot):
   a. The number of calories consumed during the day (due to ingested foods and drinks)
   b. Calories burned (from exercising, etc.)
   c. Calories we have left to consume to reach the day's goal
4. Explore and find a recipe that meets each of the following conditions:
   a. 1 vegan breakfast (between 150 and 200 kcal) and mark it as a favorite
   b. 1 vegan lunch (between 350 and 400 kcal) and mark it as a favorite
   c. See the recipes you have marked as favorites (and take a screenshot of them)

First, it is recommended that an initial profile be created and the desired weight goals be determined. Second, to add records or data pertaining to the current day, the functions available from the Daily and/or Profile menus need to be used. Third, it is requested that the number of calories consumed throughout the day be identified and recorded. This should include the calories derived from food and drink, the calories expended through exercise, and the remaining calories to be consumed to reach the daily goal. Fourth, it is required to conduct a comprehensive investigation and identify a recipe that aligns with the specific criteria outlined in step 4 in Textbox 1.

Following the completion of the tasks, the participants were invited to respond to the S-MAUQ in person using a Google Form.

The internal consistency of the S-MAUQ was evaluated by calculating the Cronbach α value for the entire questionnaire and its 3 subscales. A higher α value indicates greater internal reliability, and a value of ≥0.70 is generally considered acceptable as an indication of good internal reliability [31,32]. All statistical analyses were conducted using SPSS (IBM Corp), and the results were verified using Excel (Microsoft Corp).

Figure 1 provides an overview of the process of translation and cross-cultural adaptation as well as the subsequent validation stage for S-MAUQ'.

Ethical Considerations

No financial compensation was provided to participants at any stage of the study. Participation was voluntary and anonymous, except for members of the expert panel responsible for content validation, who were intentionally selected for their expertise. All participants (including the expert panel) were provided and signed an informed consent online, which included the possibility of opting out. The study adhered to the Declaration of Helsinki and was approved by the Bioethics Committee of the Medical University of Málaga (17 - 2022-H).

RenderX

Results

Content Validation

Please refer to Table 1, which presents the calculated values (using Excel) of the I-CVI for relevancy and clarity, the (Pc), and the modified kappa agreement (κ) by the 10 experts for each item of the S-MAUQ. The S-CVI was calculated to be 0.778. However, as can be seen, there were 2 items (#3 and #6) with κ<0.4 (interpreted as poor agreement) and 2 others (#15 and #18) with 0.4<κ<0.6 (interpreted as fair). Considering these findings, we sought to further refine the instrument in accordance with the recommendations of the expert panel.

Table . Content validity index of item relevancy and modified kappa agreement by 10 experts in round 1.

Items	Rating of 4 or 5, n	Rating of 1 to 3, n	Item-level content validity index[a]	Probability of chance occurrence[b]	Modified kappa[c,d]	Interpretation
1	10	0	1.000	0.001	1.000	Excellent
2	9	1	0.900	0.010	0.899	Excellent
3	5	5	0.500	0.246	0.337	Poor
4	8	2	0.800	0.044	0.791	Excellent
5	9	1	0.900	0.010	0.899	Excellent
6	5	5	0.500	0.246	0.337	Poor
7	10	0	1.000	0.001	1.000	Excellent
8	8	2	0.800	0.044	0.791	Excellent
9	7	3	0.700	0.117	0.660	Good
10	8	2	0.800	0.044	0.791	Excellent
11	9	1	0.900	0.010	0.899	Excellent
12	9	1	0.900	0.010	0.899	Excellent
13	8	2	0.800	0.044	0.791	Excellent
14	7	3	0.700	0.117	0.660	Good
15	6	4	0.600	0.205	0.497	Fair
16	9	1	0.900	0.010	0.899	Excellent
17	7	3	0.700	0.117	0.660	Good
18	6	4	0.600	0.205	0.497	Fair

[a]Scale content validity index=0.778.

[b]Computed using the formula Pc = [N! / (A! * (N–A)!)] * 0.5N, where Pc is the probability of chance occurrence, n is the number of experts, and A is the number of experts who agree the items are relevant/clear.

[c]Computed using the formula κ=(item-level content validity index – Pc) / (1 – Pc), where Pc is the probability of chance occurrence.

[d]Kappa was interpreted according to the following criteria: excellent, κ>0.74; good, 0.6≤κ≤0.74; fair, 0.40≤κ≤0.59; poor, κ<0.40.

The results of the second round are presented in Table 2, which indicates an S-CVI of 0.850. However, 2 items (#14 and #15) demonstrated a markedly low level of relevance and clarity (I-CVI), accompanied by a similarly low κ (0.4≤κ≤0.6, interpreted as “fair”). Following a thorough review with our panel of experts, it was determined that both items should be removed from the preliminary Spanish questionnaire (S-MAUQ). In conclusion, the S-CVI was calculated to be 0.881 (without considering the 2 items that were subsequently eliminated).

18	7	3	0.700	0.117	0.660	Good

[a]Scale content validity index=0.850.

[b]Computed using the formula Pc = [N! / (A! * (N–A)!)] * 0.5N, where Pc is the probability of chance occurrence, n is the number of experts, and A is the number of experts who agree the items are relevant/clear.

[c]Computed using the formula κ=(item-level content validity index – Pc) / (1 – Pc), where Pc is the probability of chance occurrence.

[d]Kappa was interpreted according to the following criteria: excellent, κ>0.74; good, 0.6≤κ≤0.74; fair, 0.40≤κ≤0.59; poor, κ<0.40.

Face Validation

Please refer to Table 3 for the calculated values of the I-FVI, the Pc, and the modified kappa agreement (κ) for each item. These were determined by the 12 target users. The S-FVI was calculated to be 0.927. A score >0.79 indicates that the items in the questionnaire are sufficiently clear and understandable for the nonexpert target user [27]. Furthermore, the modified kappa agreement for each item in S-MAUQ demonstrated excellent concordance (κ>0.74).

XSL•FO
RenderX

[a]Scale face validity index=0.927.

[b]Computed using the formula Pc = [N! / (A! * (N–A)!)] * 0.5N, where Pc is the probability of chance occurrence, n is the number of users, and A is the number of users who agree the items are understandable.

[c]Computed using the formula: =(item-level face validity index – Pc) / (1 – Pc), where Pc is the probability of chance occurrence.

[d]Kappa was interpreted according to the following criteria: excellent, $\kappa>0.74$; good, $0.6\leq\kappa\leq0.74$; fair, $0.40\leq\kappa\leq0.59$; poor, $\kappa<0.40$.

[e]Removed from the questionnaire.

[f]Not applicable.

Reliability (Internal Consistency) Validation

A total of 61 participants completed the web-based consent form and the S-MAUQ questionnaire for the purposes of the reliability study (the calculated sample size was 48). The participants were between the ages of 18 years and 22 years, and all were students (41 men, 20 women). The mean usability score (normalized to 1) for the Yazio app, as determined by the S-MAUQ, was 0.855 (SD 0.088). This indicates a high level of usability.

The Cronbach α value for the entire S-MAUQ was 0.87, and the values for the 3 subscales were 0.74 for the ease of use dimension (Q1-Q5), 0.74 for the interface and satisfaction dimension (Q6-Q12), and 0.64 for the usefulness dimension (Q13-Q16). The new numbering scheme was used for Q13-Q16, omitting the 2 deleted items.

Furthermore, the Cronbach α value for the complete questionnaire remained highly consistent when an item was deleted (see Table 4), indicating that the S-MAUQ exhibited good internal reliability.

XSL•FO
RenderX

Table . The internal consistency of the item's total statistics.

Items	Scale mean if item deleted[a]	Scale variance if item deleted	Corrected item total correlation	Cronbach α if item deleted[b]
1	89.46	87.086	0.532	0.854
2	89.07	85.129	0.635	0.850
3	89.10	85.190	0.570	0.852
4	89.07	87.562	0.470	0.857
5	89.15	84.061	0.462	0.859
6	88.90	89.323	0.345	0.863

15[c]	—	—	—	—
16	89.20	87.961	0.451	0.858
17	90.00	85.033	0.429	0.860
18	89.33	85.324	0.525	0.854

[a]Overall scale mean=95.21.

[b]Overall scale Cronbach α=0.87 (high internal consistency); ease of use subscale (Q1..Q5) Cronbach α=0.74; interface and satisfaction subscale (Q6..Q12) Cronbach α=0.74; usefulness subscale (Q13, Q16..Q18) Cronbach α=0.64.

[c]Removed from the questionnaire.

[d]Not appliclable.

Discussion

Principal Findings

Ensuring optimal usability of Spanish mobile apps is one of the most crucial factors for their use. Questionnaires are a common method for evaluating usability. This study outlined the process of translating, adapting, and validating the English version of the standalone MAUQ questionnaire for the patient into Spanish.

To this end, we followed the 4-step process proposed by Sousa and Rojjanasrirat [20], as it was outlined in the Methods section.

During the translation and adaptation phase, several meetings were held to ensure conceptual and linguistic equivalence for key terms such as interface, consistency, coherence, social setting, and health and well-being services. Final wording was established by consensus, often in consultation with the original questionnaire's authors.

In the content validation phase, the expert panel initially did not reach full agreement on several items. A second round of review narrowed the discrepancies but left 2 items (#14 and #15) unresolved. Both items were judged to be conceptually ambiguous and difficult to interpret, even for experts. Following a series of email consultations with the original authors on the meaning of and convenience of these items and their overlap with others, we confirmed the experts' results and their suggestions that these items could be removed from the final Spanish version.

During the face validation phase, the calculated FVI and κ coefficient yielded an S-FVI that substantially exceeded the recommended threshold, thereby ensuring the quality of the translation. The results of the study indicated that the items on the questionnaire were comprehensible and suitable for the target population.

Finally, the reliability analysis demonstrated strong internal consistency, with an overall Cronbach α of 0.87. The Spanish version maintained the original 3-dimensional structure of the English questionnaire, permitting direct cross-language comparison. Only the "usefulness" dimension was slightly affected, with an acceptable Cronbach α of 0.64 for exploratory studies. Overall, the S-MAUQ exhibited sound psychometric properties, indicating that it is a reliable and valid tool for assessing the usability of mobile health apps among Spanish-speaking patients. The final iteration of the S-MAUQ is presented in Table 5 for reference.

Table . The final Spanish version of the mHealth App Usability Questionnaire (S-MAUQ).

Item number	Question
1	La aplicación era fácil de usar.
2	Me resultó fácil aprender a utilizar la aplicación.
3	Al pasar de una pantalla a otra, la navegación era consistente, similar, previsible.
4	La aplicación me permitió usar todas las funciones que necesité (tales como visualizar e introducir información, responder a recordatorios, etc).
5	Cuando cometí un error usando la aplicación, fue fácil y rápido deshacerlo y volver a intentarlo.
6	Me gusta el diseño y aspecto de la aplicación.
7	La presentación de la información en la aplicación estaba bien organizada, y me permitió encontrar lo que buscaba.
8	La aplicación mostraba adecuadamente el progreso de mi actividad mientras interactuaba con ella.
9	Me sentiría cómodo/a utilizando esta aplicación en público, delante de otras personas.
10	El tiempo invertido en realizar las tareas deseadas me ha parecido adecuado.
11	Volvería a utilizar esta aplicación.
12	En general, estoy satisfecho/a con esta aplicación.
13	Creo que la aplicación puede ser útil para mi salud y bienestar.
14 (#16 in MAUQ)	Esta aplicación tiene todas las funciones que esperaba.
15 (#17 in MAUQ)	He podido realizar algunas tareas incluso cuando la conexión a internet era mala o no estaba disponible.
16 (#18 in MAUQ)	Esta aplicación me proporcionó una forma aceptable de recibir servicios de salud, tales como el acceso a material educativo, el seguimiento de mis actividades, o la realización de autoevaluaciones.

Comparison With Prior Research

Our findings align with prior validations of the MAUQ conducted to assess a variety of mobile apps developed for different purposes and user groups, including the MyFitnessPal in Malaysia for evaluating caloric intake, weight goals, and nutritional guidance [16]; the Left-Handed Doctor mHealth app in China for medical consultations and public health guidance [33]; the Enable app in Germany for cancer patients to register electronic patient-reported outcomes and monitor treatment side effects [17]; and the DIGICOG-MS app in Italy for cognitive assessment of individuals with multiple sclerosis [18] and patients with osteoporosis in the Persian study [34]. Collectively, our findings suggest that both the MAUQ and S-MAUQ demonstrate stable content validity across diverse contexts and could be applied to a wide range of mHealth and eHealth applications designed for different populations.

It is noteworthy that a Spanish adaptation [19] developed in parallel with our own work has not adhered to the MAUQ standard; instead, it was adapted for breastfeeding. Several items have undergone alterations and been reordered, and one item was eliminated. The original dimensions were modified from 3 to 4, but the results indicate a significant lack of internal consistency in 2 final subscales. Furthermore, there was an erroneous interpretation and implementation of the formula applied to calculate the level of relevance and clarity of the questionnaire items. Consequently, it was not possible to achieve comparable outcomes in different languages.

We also compared our work with the aforementioned studies that focus on the “standalone, for patients” version of the MAUQ. The Malaysian version of the MAUQ [16] underwent an analysis similar to ours, maintaining the 3-dimensional structure but without eliminating any element. The German version of the MAUQ [17] also performed a study similar to ours and to that of the Malaysian version. However, the creators of the German version considered eliminating 1 item but finally decided not to do so in order to maintain consistency with the original. The Italian version [18] did not undergo content or face validation; they had a panel of 6 experts who directly compared a translated version with the original questionnaire and made modifications to have a more understandable Italian version.

Limitations

In our study, as in other similar work [16], we surveyed a large sample of native Spanish-speaking students to provide a representative sample of the young adult demographic. In future research, criterion validation studies should be conducted to predict different outcomes for different domains and types of users of the S-MAUQ.

XSL•FO
RenderX

Conclusions

We addressed a significant gap in the field of health app evaluation in Spanish by translating and adapting the MAUQ, one of the most recognized usability questionnaires in this area. Despite the need to eliminate 2 items due to their lack of relevance and demonstrated confusion, S-MAUQ is a reliable tool in Spanish for evaluating the usability of mHealth apps.

Acknowledgments

We would like to thank Dr. L. Zhou for granting us permission to translate the mHealth App Usability Questionnaire (MAUQ) into the Spanish version, his help during the translation process, and clarifying some of the items in the questionnaire. Thank you also for conveying to us the interest and the various requests that he received from individuals and research groups interested in having the questionnaire available in Spanish. We also thank the panel of experts and the other participants involved in this study.

Abstract

Background: There is growing recognition of the role of health apps in addressing health care system challenges, yet app quality and evidence vary widely, and consumers have little decision support at the point of download.

Objective: This study aimed to explore which sources of recommendations European residents use and trust when choosing health apps and whether residents support government review and rating of health apps.

Methods: We conducted a cross-sectional online survey (December 7, 2022, to February 16, 2023) in 26 languages targeting residents of the European Economic Area, the United Kingdom, and Ukraine. The survey contained 11 questions covering demographics, types of apps used, sources of advice used and trusted, and views on government review and rating. We included only fully completed responses (N=1228). Descriptive statistics are presented as counts and percentages. For subgroup analyses, we dichotomized trust responses (“I trust” vs other responses) and tested associations with gender (Fisher exact test), age group, and education level (chi-square test); an adjusted significance threshold was applied (P<.004) to account for multiple testing. We followed the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) guidelines for reporting online surveys and STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) recommendations for observational studies.

Results: A total of 1228 respondents from 33 countries completed the survey; 1110 (90.4%) reported using one or more health apps. COVID-19 apps (763/1228, 62.1%) and activity apps (737/1228, 60.0%) were the most frequently used, whereas disease management (86/1228, 7.0%), diagnostic (77/1228, 6.3%), and treatment apps (70/1228, 5.7%) were the least used. Sources used to choose apps included family and friends (434/1228, 35.3%), health professionals (412/1228, 33.6%), and government or health authorities (358/1228, 29.2%). The most trusted sources were health professionals (987/1228, 80.4%), pharmacists (750/1228, 61.1%), and government or health authorities (736/1228, 59.9%). No statistically significant differences in trust by gender were observed (all P>.0038). Some differences by age and education were observed for select sources (eg, government or health authorities: χ^2_1=8.546; P=.003; family and friends: χ^2=19.133; P<.001). Overall, 1060 (86.3%) of 1228 respondents supported government review and rating of health apps (either directly or by commissioning another organization).

Conclusions: In this large multilingual European survey, most respondents reported experience with health apps and placed greatest trust in health professionals, pharmacists, and government or health authorities, yet professional recommendations were used less often than informal sources. There is clear public support for government-led review and rating schemes to guide consumer choice. Efforts to make trustworthy, easy-to-find information available at the point of download and to support health care professionals in recommending high-quality apps could help bridge the gap between trusted and used sources.

Introduction

Overview

Health systems in Europe face multiple challenges including aging populations, growing chronic disease burdens, rising costs, and workforce shortages. Digital health tools such as health and wellness apps ("health apps") are increasingly proposed as part of the response to these pressures [1]. The number of available health apps is large and growing (estimated >350,000 in app stores in 2020), but app quality and the underlying evidence base vary widely [2-4]. Consumers typically have limited reliable information at the point of download beyond app descriptions and star ratings, which do not reliably indicate clinical validity or safety [5-8].

One path to increasing public confidence in health apps is through recommendations from trusted sources (eg, clinicians or health authorities). Experimental and observational research indicates that who recommends an app affects the intention to download it and that clinicians are often trusted but may lack time, training, or trustworthy sources to recommend apps [9-14]. To date, evidence on which sources European residents actually use and trust is limited. This gap motivated the present cross-European survey, carried out as part of the Horizon Europe Label2Enable project, which aims to promote the newly developed [15] CEN-ISO/TS 82304-2:2021 health app quality framework [16].

Study Objectives

The primary objectives of this study were as follows:

- Identify which sources European residents use to choose health apps
- Identify which sources European residents trust when choosing health apps
- Assess whether residents think the government should review and rate health apps to support choice

The secondary objective was to explore differences in trust by gender, age group, and educational level.

Methods

Design and Participants

We conducted a cross-sectional online survey between December 7, 2022, and February 16, 2023, using the Castor electronic data capture system. Eligible participants were residents (aged ≥18 years) of the European Economic Area, the United Kingdom, or Ukraine who could read and respond to a digital survey. No further inclusion or exclusion criteria were applied. The survey was open for 10 weeks and was promoted via the Label2Enable project website, project partners, and social media channels. Because the study was exploratory and descriptive, we did not perform a sample size calculation; however, recruitment and dissemination were monitored to seek diversity across countries, age, gender, and education.

Survey Instrument

The 11-item survey (Multimedia Appendix 1) covered sociodemographic characteristics (country of residence, year of birth, gender, education level, self-reported health, and informal caregiver status); types of health apps used (17 options); sources of advice used to choose apps (15 options; multiple selections allowed); trust in the same sources (4-point Likert scale); and views on government review and rating (3 options). One open-ended question solicited final thoughts. The English version was drafted in plain language; professional translators translated the survey into 25 other languages (covering 22 of 24 official European Union languages plus Norwegian, Ukrainian, Arabic, and Turkish). Translations were validated by native speakers with expertise in digital health.

Ethical Considerations

The Medical Ethics Committee of Leiden–Delft–The Hague reviewed the study and waived the need for full ethics approval (reference 223069; November 14, 2022). Participants provided informed consent by completing an online consent statement before starting the survey; they were informed that participation was voluntary, responses were anonymous, and they could withdraw by closing the browser before submission. No personal identifiers were collected. Aggregate data were stored and analyzed in deidentified form. No compensation was offered to participants.

Translation and Dissemination

Separate language-specific links were hosted on the Label2Enable website, and social media assets were provided to project partners (eg, European Patients' Forum and EuroHealthNet) to assist dissemination. Response rates were monitored biweekly, and dissemination tactics were adjusted accordingly.

Statistical Analysis

Only fully completed surveys were included in the analysis (N=1228). Descriptive statistics were presented as counts and percentages; means and SDs were reported for continuous variables (age). To examine associations between demographic variables (gender: male, female, nonbinary, or other; age: 18 - 65 vs >65 years; education: low [high school or less or practical training] vs high [bachelor's, master's, or doctoral degree]) and trust in different sources, we dichotomized trust responses into "I trust" versus all other responses. For gender, we used the Fisher exact test when expected cell counts were small; for age and education, we used chi-square tests. Because multiple related tests were performed, we applied a Bonferroni-style adjusted significance threshold (α adj=0.05/13=.0038) [17]. All statistical analyses were performed in SPSS (version 27; IBM Corp). For qualitative data (open-ended comments) responses were translated to English using DeepL (DeepL SE) and subjected to thematic analysis following the Braun and Clarke six-step approach [18]. We followed the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) guidelines for online surveys and STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) for reporting cross-sectional observational studies.

Results

Respondents' Characteristics

A total of 1228 fully completed responses from 33 countries were included (Multimedia Appendix 1 lists countries and counts). The median age was 47.0 (mean 47.0, SD 14.8) years; 178 (14.5%) were aged 65 years or older. Most respondents were female (787/1228, 64.1%). Education was skewed toward higher education: 1001 (81.5%) of 1228 respondents reported a bachelor's, master's, or doctoral degree. Self-reported health was good or very good for 856 (69.7%) of 1228 respondents. A quarter (318/1228, 25.9%) of the respondents provided informal care at least occasionally (Table 1).

Table . Respondents' characteristics (N=1228).

Characteristics	Values
Age (y), mean (SD)	47.0 (14.8)
Age (y), n (%)	
65 or older	178 (14.5)
18 - 65	1050 (85.5)
Gender, n (%)	
Male	438 (35.7)
Female	787 (64.1)
Nonbinary	3 (0.2)
Education level, n (%)	
High school or less	121 (9.9)
Practical or vocational education	106 (8.6)
Bachelor's, master's, or doctoral or similar	1001 (81.5)
Self-reported health status, n (%)	
Poor	76 (6.2)
Fair	206 (24.1)
Good	592 (48.2)
Very good	264 (21.5)
Informal care, n (%)	
I provide informal care every day	106 (8.6)
I provide informal care at least once a week	78 (6.4)
I provide informal care, but not every week	134 (10.9)
I do not provide informal care	910 (74.1)

Use of Health Apps

Overall, 1110 (90.4%) of 1228 respondents reported using one or more health apps. The most used app types were COVID-19 apps (763/1228, 62.1%) and activity apps (737/1228, 60.0%). Disease management apps (86/1228, 7.0%), diagnostic apps (77/1228, 6.3%), and treatment apps (70/1228, 5.7%) were the least used (Table 2).

XSL•FO
RenderX

Table . Types of health apps used by respondents (multiple responses allowed; N=1228).

Type of health apps	Values, n (%)
COVID-19 app	763 (62.1)
Activity app	737 (60.0)
Health insurance app	446 (36.3)
Hospital or clinic app	417 (34.0)
Nutrition app	297 (24.2)
Personal health record app	271 (22.1)
Sleep app	270 (22.0)
Menstruation app	265 (21.6)
Vital signs app	217 (17.7)
Mindfulness app	186 (15.1)
Disease management app	86 (7.0)
Diagnostic app	77 (6.3)
Treatment app	70 (5.7)
Research app	68 (5.5)
Informal caregiver app	19 (1.5)
Other	68 (5.5)
I do not use a health app	118 (9.6)

Sources of Advice Used to Choose Health Apps

Respondents reported using recommendations from family and friends (434/1228, 35.3%), health professionals (412/1228, 33.6%), and government or health authorities (358/1228, 29.2%) more often than curated sources such as health app libraries (72/1228, 5.9%) or pharmacists (97/1228, 7.9%; Table 3).

Table . Sources of advice or tips used to choose a health app (multiple responses allowed; N=1228).

Source of advice	Values, n (%)
My family and friends	434 (35.3)
A health professional	412 (33.6)
A government or health authority	358 (29.2)
The App Store or Google Play store	291 (23.7)
A Google search	282 (23.0)
A health professional organization	247 (20.1)
Personal social media posts	183 (14.9)
A patient organization	163 (13.3)
Traditional media	155 (12.6)
A peer support group	129 (10.5)
A health app manufacturer	109 (8.9)
A pharmacist	97 (7.9)
A health app library	72 (5.9)
None of the above	88 (7.2)
Other	54 (4.4)

Trust in Sources of Advice

When asked which sources they trusted, respondents indicated the highest trust for health professionals (987/1228, 80.4%), pharmacists (750/1228, 61.1%), and government or health authorities (736/1228, 59.9%). Low trust was reported for personal social media posts (65/1228, 5.3%), app stores (144/1228, 11.7%), Google search (118/1228, 9.6%), and health app manufacturers (113/1228, 9.2%; Table 4).

XSL•FO

Traditional media	303 (24.7)	635 (51.7)	161 (13.1)	129 (10.5)
The App Store or Google Play store	370 (30.1)	591 (48.1)	144 (11.7)	123 (10.0)
A Google search	358 (29.2)	667 (54.3)	118 (9.6)	85 (6.9)
A health app manufacturer	351 (28.6)	651 (53.0)	113 (9.2)	113 (9.2)

Differences in Trust by Gender, Age, and Education

The Fisher exact test showed no statistically significant differences in trust by gender across the 13 tested sources at the α adj=.0038 level (all $P>.0038$). Chi-square tests for age and education showed some statistically significant differences for selected sources (eg, government or health authorities: $\chi^2_1=8.546$; $P=.003$; family and friends: $\chi^2_1=19.133$; $P<.001$; health app libraries: $\chi^2_1=8.249$; $P=.004$). However, when applying the adjusted threshold, only $P\leq.0038$ was considered statistically significant. Refer to Table 5 for full stratified results and *P* values.

Chi-square analyses indicated that levels of trust in most sources of advice did not differ substantially across age groups (Table 4). Notable exceptions included government and health authorities ($\chi^2_1=8.55$; $P=.003$), family and friends ($\chi^2_1=19.13$; $P<.001$), health app libraries ($\chi^2_1=8.25$; $P=.004$), app stores ($\chi^2_1=4.12$; $P=.04$), Google searches ($\chi^2_1=5.38$; $P=.02$), and health app manufacturers ($\chi^2_1=4.82$; $P=.03$), where significant differences were observed. Similarly, no consistent differences were found between education levels, although significant variation was detected for government and health authorities ($\chi^2_1=13.02$; $P<.001$) and health professional organizations ($\chi^2_1=8.07$; $P=.005$). Full test statistics for all sources of advice are presented in Table 5.

Views on Government Review and Rating of Health Apps

Among the 1228 respondents, a total of 1060 (86.3%) respondents indicated that either the government should review and rate health apps (n=664, 54.1%) or that the government should pay another organization to do so (n=396, 32.2%); 168 (13.7%) opposed government involvement (Table 6).

Table . Views on whether the government should review and rate health app quality (N=1228).

Response options	Values, n (%)
Yes, I think the government should review and rate health app quality	664 (54.1)
No, but I think the government should pay another organization to review and rate health app quality	396 (32.2)
No, I think the government should not review and rate health app quality and should not pay another organization to review and rate health app quality	168 (13.7)

Thematic Analysis of Open Comments

Of 1228 respondents, 213 (17.3%) provided free-text comments. Thematic analysis identified 3 main themes [19].

The first theme was exploring apps as a useful part of health care (prescription, reimbursement, and accessibility). Respondents expressed that apps should be prescribed and reimbursed to ensure their continuous improvement and that they should be made accessible to all patients. Health professionals should consider using data and apps to improve their work.

The second theme was identifying the need for quality assessment and transparency (certification and evidence), represented by this quote: “If you want something to work, you have to evaluate it.” Some referred to their role: “I would accept every recommendation first and then research the app myself and test it.” Few saw no need for an assessment: “Bad apps eventually phase themselves out as they increasingly turn out to be bogus.” or “The quality of the health apps can easily be assessed by health care professionals. I think it’s a waste of money to put much effort into this.”

The third theme revolved around who should review and rate apps (preference for independent and knowledgeable assessors). Respondents expressed mixed views; some mentioned assessors should be independent with a high ethical standard, have no interest in the app, and have extensive knowledge of both the clinical subject of the app, information and communication technology, and data privacy. Suggestions included a research institute without commercial interests with a high degree of transparency. Others indicated difficulty in identifying any trusted entity to review and rate apps. One comment summarized the 3 themes in one sentence: “Trust in health apps comes from certifications, scientific evidence, and the authorities’ approval and implementation.”

Discussion

Principal Findings

In this large multilingual European sample (N=1228), the majority reported prior or current use of health apps; COVID-19 apps and activity or wellness apps were the most common. Health professionals, pharmacists, and government or health authorities were the most trusted sources of advice, yet professional recommendations were used less often than informal sources such as family and friends. A strong majority favored government involvement in reviewing and rating apps to support consumer choice.

Used and Trusted Sources of Advice

Our findings echo prior studies from Australia and Europe that show clinicians are highly trusted but seldom provide app recommendations due to the lack of time, training, and accessible appraisal tools [9-14,20]. One could expect that people would use advice from sources they trust most. However, this discrepancy suggests a limited availability of professional recommendations despite high levels of trust in clinicians. In an Australian study, general practitioners highlighted the lack of knowledge of effective health apps and the lack of trustworthy sources to access high-quality apps as the 2 main barriers to prescribing or providing relevant health app advice [21-23]. A possible solution is to require app stores to display a health app label showing the app’s performance using standardized scales or to create curated health app libraries.

The observed high trust in pharmacists is consistent with literature pointing to pharmacists as potential contributors to digital health counseling [24]. Low public awareness and use of app libraries reflect earlier reports that curated portals are poorly known despite conceptual appeal [25]. Awareness of health app libraries remains limited. For example, one study reported that participants were unfamiliar with the concept of app portals or curated app libraries.[26] Although the idea of curated app repositories indexing government-evaluated and approved apps is appealing, existing initiatives have not yet fully met user needs. The National Health Service for instance, discontinued its central app library and instead integrated recommendations across its website to highlight apps that are already widely used and trusted. Other national initiatives include France’s *Mon Espace Santé* and Germany’s DiGA (*Digitale Gesundheitsanwendungen*; Digital Health Application) directory [27]. Despite the limited uptake among prescribers—only 4% of physicians in Germany had prescribed a DiGA as of early 2022 patient-reported experiences are encouraging: 63% reported a favorable clinical outcome, and 86% indicated willingness to use another DiGA in the future [28,29]. These findings suggest that curated health app libraries, when built on transparent and endorsed evaluation frameworks and made easy to access and navigate, could play an important role in guiding user choice and promoting the safe integration of digital health tools.

Implications for Policy and Practice

Three implications follow. First, governments and health authorities should consider transparent, evidence-based review and rating schemes (or commissioning trusted independent bodies) and ensure that appraisal results are visible at the point of download. Second, health professionals and pharmacists should be supported with accessible, up-to-date appraisal information and implementation support so they can confidently recommend high-quality apps. Third, further research should test which review and rating mechanisms most effectively change consumer behavior and health outcomes; public preference alone does not establish effectiveness.

Strengths and Limitations

Strengths include the large multilingual survey, the inclusive plain-language survey instrument, and mixed quantitative and qualitative analysis. A limitation of this study is that the sample was self-selected and skewed toward highly educated respondents, with overrepresentation from some countries (eg, the Netherlands: 403/1228, 32.8%), which limits generalizability. The mean age (47.0, SD 14.8 years) is older than many app user samples and may affect observed patterns of app types and trusted sources. These points are discussed and flagged as limitations. We did not apply poststratification weights to achieve population representativeness; given the exploratory aim, we report unweighted descriptive results but caution against overgeneralization. The thematic analysis was

XSL•FO
RenderX

performed on English translations of free-text responses, which may have influenced coding.

Conclusions

European residents in this large multilingual survey frequently use health apps and place greatest trust in clinicians, pharmacists, and government or health authorities—yet trusted sources are used less often than informal sources. There is clear public support for government-led review and rating or the commissioning of independent organizations to evaluate apps. Policymakers should prioritize transparent, accessible appraisal systems and strategies to support clinicians and pharmacists in recommending high-quality apps.

Acknowledgments

The study team thanks all consortium members of the Label2Enable project and partner organizations who assisted with recruitment and dissemination.

Funding

This study was conducted as part of the Horizon Europe Label2Enable project (Label2Enable). The project is supported by funding from the European Commission under the Horizon Europe programme. The funder had no role in study design, data collection, analysis, manuscript preparation, or decision to publish.

Data Availability

The aggregated deidentified dataset generated and analyzed during this study is available from the corresponding author on reasonable request. Multimedia appendices (including survey instrument, country list, and thematic quotes) are provided.

Abstract

Background: eHealth is an increasingly used method of health care in the field of psycho-oncology. While many reports highlight the positive impact of psychological eHealth tools, some patients refuse to use them.

Objective: This study aimed to expand knowledge of the motivation and psychoemotional functioning of patients who consciously refuse to use eHealth technology in the form of a mobile psycho-oncology app offered as part of a clinical trial. To our knowledge, this is the first study to address this topic.

Methods: A retrospective cross-sectional study was conducted between December 2022 and February 2023 to investigate the reasons why 56 patients with breast cancer refused to use the psycho-oncology mobile app offered as part of a clinical trial by the Breast Cancer Unit. The primary aim of the study was to analyze patients' self-reported reasons for not engaging with the app, while also exploring their psychoemotional functioning, including stress levels (measured using the distress thermometer), personality traits (measured using the Ten-Item Personality Inventory), coping strategies (measured using the Coping Orientation to Problems Experienced Questionnaire), and Self-efficacy (measured using the General Self-Efficacy Scale). Participants in this study declined the app intervention but agreed to participate in this separate observational study, indicating that their refusal was related to the app itself rather than to participation in clinical research in general.

Results: The patients experienced a clinically meaningful elevation in stress levels (mean 5, SD 2.1 points) and Self-efficacy (mean 32.1, SD 5.1 points). Among 5 dimensions of personality traits, patients scored highest in Agreeableness (mean 6.5, SD 0.8 stens) and Conscientiousness (mean 6.4, SD 0.9) and lowest in Neuroticism (mean 3.4, SD 1.8) (other dimensions: Extraversion [mean 5.8, SD 1.6 stens] and Openness to Experiences [mean 4.4, SD 1.5 stens]). In terms of coping with stress, patients most frequently used the strategies of Active Coping (mean 2.6, SD 0.5 points), Acceptance (mean 2.6, SD 0.6 points), and Seeking Emotional Support (mean 2.6, SD 0.6 points), and least frequently used the strategies of Psychoactive Substance Use (mean 0.2, SD 0.6 points) and Restraint (mean 0.5, SD 0.7 points). Patient responses regarding refusal to participate in app testing were divided into four categories: (1) Focus on Life Outside the Disease, (2) Focus on Disease and Treatment, (3) Denial Mechanism, and (4) Technical Issues. Statistically significant differences were found between the groups. The Focus on Life Outside the Disease group of patients had higher levels of Self-efficacy, lower Neuroticism, and more frequent use of the Positive reevaluation strategy compared to the other groups.

Conclusions: Our patients' decision not to use the eHealth psycho-oncology app was mainly influenced by characteristics suggesting better emotional coping with the disease and treatment. These factors were significantly more influential than other factors studied, particularly those related to technology. Assessing reasons for opting out of eHealth and associated psychomotional functioning may be important for improving patients' adoption of eHealth solutions.

Introduction

Electronic communication–based tools (eHealth) are a method of providing health care services using web-based technologies [1]. eHealth has been developing for more than a decade [2-5]. Originally designed to expand access to health care through remote contact and reduce costs, during the COVID-19 pandemic, these solutions became increasingly common and entered the mainstream of care due to the requirements of social isolation [6]. The solutions developed during this period have proved beneficial to the health care system in terms of time, premises, and economy. Researchers emphasize widespread availability, improved health monitoring among the public, and increased awareness of healthy lifestyles and ways to prevent diseases and other undesirable psychological conditions [2,3]. Many reports indicate the positive impact of psychological eHealth tools, highlighting a number of their advantages [7-11]. eHealth solutions are also increasingly being used in specific areas of health care, such as psycho-oncology [2,12]. Their goal is to improve psychological well-being both during and after oncological illness. Most of these tools are based on the tenets of cognitive-behavioral therapy and are constantly being developed [13].

The number of publications regarding barriers to the use of eHealth technologies is lower than that outlining its advantages [14]. Most emphasize significant barriers, including inability to access the technology, lack of time for patients and clinicians, and lack of patient motivation or need to use it [14-16]. However, fears associated with the risk to privacy for health-related data, lack of trust in algorithm-based approaches, and the absence of optimal, safe, and trustworthy channels for the dissemination of distant eHealth tools are also vital potential limitations.

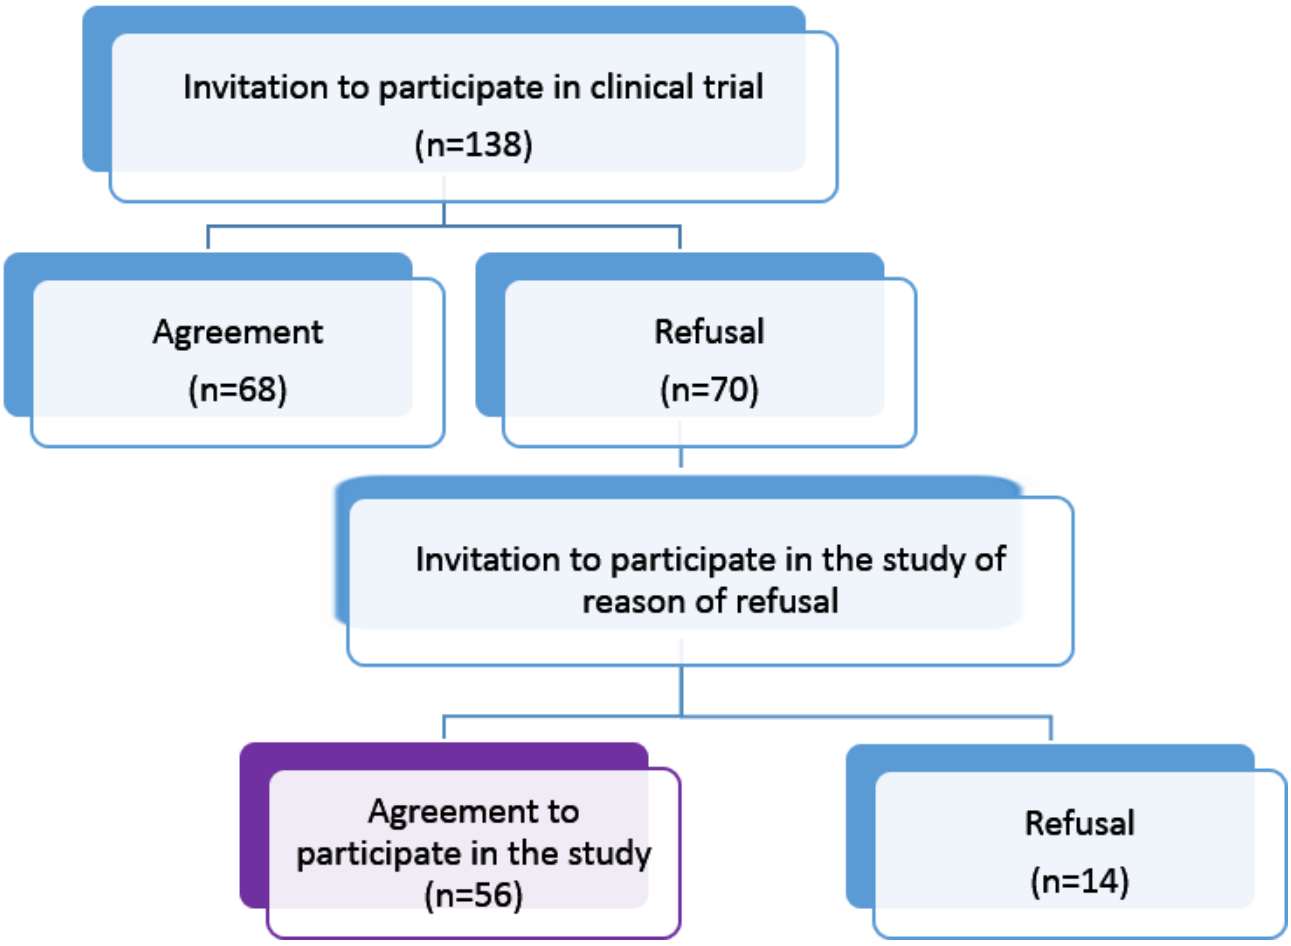
Few publications address the barriers associated with using eHealth solutions in the field of psycho-oncology, and even fewer provide evidence specific to cancer types [2]. In a comprehensive systematic review of eHealth technologies for breast cancer supportive care, Gyawali et al [2] identified only 2 studies reporting information on barriers to the use of eHealth interventions. These studies mention 2 groups of barriers. The first group is related to the failure to meet the necessary conditions for effective use of eHealth, including awareness of, openness to, and trust in eHealth among both patients and staff, digital competence, and a clear legal framework. The second group of barriers is mainly related to the disadvantages reported by patients during use, such as technical problems, mismatch between content and stage of treatment, lack of certain information, and discomfort with the lack of face-to-face contact.

In another recent review by Horn et al [17] on breast cancer survivors, 8 trials were identified that reported reasons for dropouts. The most frequent reason was time constraints, followed by unmet expectations of participants, technical problems, and physical and psychological health. In addition, researchers note the lack of uniform assessment scales for the usefulness of eHealth tools, and existing assessments mainly focus on technical aspects [18]. They also highlight that professionals have their own barriers to using eHealth [19].

Most studies on barriers to the use of eHealth in psycho-oncology have been conducted among patients who have used such solutions, reporting their perceived advantages and disadvantages [2,17]. We found only 1 survey that explicitly addressed patients who refuse to use such solutions [20]. This group of patients seems particularly interesting because of the growing demand for eHealth and the prospect that, in the near future, some interventions will only be possible using eHealth. Gupta et al [20] described only challenges in the recruitment process. Our goal was to expand knowledge of the motivation and psychoemotional functioning of patients who consciously refuse to use eHealth technology in the form of a mobile psycho-oncology app offered as part of a clinical trial. Specifically, we examined reasons for refusal and assessed patients' stress levels, Self-efficacy, personality traits, and coping strategies. Importantly, all participants included in this study declined the mobile app intervention but agreed to participate in a separate observational study related to psychoemotional functioning. This distinction indicates that their refusal was specific to the app itself rather than to a general reluctance to participate in clinical research. Therefore, this study aimed to explore and categorize the reasons for refusal of a mobile psycho-oncology app among patients with primary breast cancer and to examine the psychoemotional functioning associated with different refusal categories. To the best of our knowledge, this is the first study of its kind.

Methods

Materials and Procedure



We conducted a retrospective study at the Breast Cancer Unit of the National Research Institute of Oncology in Gliwice, Poland, between February 2022 and November 2022. During this period, 138 patients with primary early-stage breast cancer at the beginning of the treatment process were offered participation in a clinical trial involving the use of a psycho-oncology mobile phone app. The clinical trial ran from February 2022 to May 2023. This clinical investigation concerned a medical device; therefore, in accordance with regulatory requirements for medical device trials, it was not assigned a clinical trial registration number (eg, European Union Drug Regulating Authorities Clinical Trials database). The app aimed to support the adaptation to the diagnosis and treatment of cancer based on cognitive-behavioral therapy. It comprised 22 visually appealing lessons, practical exercises (breathing exercises, imagery-based exercises, values-based activities, mindfulness exercises, and gratitude practice), emotion monitoring, and practical information and tips. The app was introduced to patients through a short video and was provided at no cost to those who agreed to join the clinical trial to evaluate its effectiveness. The details of the intervention are described elsewhere [21], and the final trial analysis is pending.

This report specifically focuses on patients who declined to use the mobile app within the clinical trial. Of the 138 female patients who were offered participation in the trial, 70 (51%) refused to use the app. A subsequent study involving individuals

XSL•FO
RenderX

who declined to use the app was conducted from December 2022 to February 2023. Of the 70 patients who declined, 56 agreed to participate in this study. Notably, among the remaining 14 patients who declined to participate, 6 did not attend the study appointment, and 5 provided no reason for their refusal other than unwillingness to be tested. These individuals may be considered potentially reluctant to participate in research in general. In contrast, 56 patients agreed to participate in our study, which suggests that their previous refusal was not driven by a general aversion to research but rather by specific concerns or disinterest regarding the mobile app intervention. In addition, 3 patients declined participation because of significant deterioration in health and severe pain symptoms, making it impossible to engage with a psychologist. The study recruitment and selection process is provided in Figure 1. The reporting of this observational study follows the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines.

Figure 1. Flowchart of study selection for evaluating the mobile psycho-oncology app among patients with primary breast cancer, Gliwice, Poland (2022-2023).

Measures

Demographic and Clinical Factors

Each participant answered survey questions regarding demographic issues, including age, marital status, and parental status. We reviewed patients' electronic medical records to obtain data regarding cancer diagnosis, treatment stage, date of diagnosis, and initial level of distress measured during the initial psychological interview conducted routinely for all patients at the local Breast Unit.

Reasons for Refusal

Reasons were collected using an open-ended question specifically constructed and designed for this study. Patients were asked: "Please indicate the main reason why you decided not to use the psycho-oncology mobile app offered as part of the study." Participants provided their responses in writing during an individual session conducted in the presence of a clinical psychologist, who was available to clarify instructions and provide support if needed. The assessment session took place during a subsequent hospital visit, separate from the encounter in which the patient initially declined participation in the mobile app trial. Two clinical psychologists independently coded the responses, identifying a total of 10 categories of refusal reasons. The categorization followed a data-driven process: each psychologist reviewed the answers separately and generated preliminary codes reflecting the core meaning of participants' statements. Discrepancies were resolved through consensus discussion. These initial codes were then grouped into broader thematic categories based on conceptual similarity and clinical relevance. Where applicable, the process was informed by previous literature, particularly Gupta et al [20], who described barriers to the adoption of eHealth interventions among patients with breast cancer. While most of our categories corresponded to domains identified in earlier research, one

XSL•FO
RenderX

clinically important category—reluctance to recall disease-related content—emerged uniquely from our data and is discussed further in the "Discussion" section. Importantly, the responses captured in this process referred specifically to the patients' decision to decline the mobile app, not to research participation in general. This combined approach ensured that the final categorization was both empirically grounded and clinically meaningful. The thematic categories identified through this process are summarized in Textbox 1, which presents the clinically relevant reasons for declining the psycho-oncological app.

Textbox 1. Reasons for refusal to use the psycho-oncological app within the clinical trial, Gliwice, Poland (2022 - 2023).

Lack of time—childcare responsibilities:

- Participants reported limited time due to childcare responsibilities, such as having a small child and being unable to find time for additional activities.

Lack of time—difficult family situation:

- Some respondents were engaged in caring for a disabled family member, including a disabled mother, child, or spouse.

Lack of time—demanding job:

- Several participants indicated being highly absorbed in professional work, describing their jobs as very responsible and demanding, leaving no available time.

Lack of time—frequency of medical appointments:

- Frequent medical examinations, consultations, and hospitalizations resulted in a lack of time for further commitments.

Poor physical and mental well-being:

- Respondents described mental exhaustion and poor physical condition, limiting their ability to focus on additional tasks.

Reluctance to recall disease-related content:

- Some participants did not wish to think about their illness at home and preferred to avoid disease-related content.

No mental need, feeling good:

- Several patients reported not feeling a need for psychological support or that the diagnosis did not significantly affect their well-being, reducing interest in a psycho-oncology app.

Reluctance toward new technologies:

- Some respondents expressed reluctance to use new technologies and a lack of interest in mobile apps.

Refusal to phone contact:

- Reasons included not having a private mobile phone or being unable to install non–work-related apps.

Other reasons:

- This category included various individual reasons, such as already receiving sufficient support through long-term psychotherapeutic treatment.

The process involved categorizing the responses into overarching categories based on the focus of the patients' concerns and reasons for refusal. The essential criterion for assignment to the various categories was the primary reason behind the refusal, as identified by 2 independently working psychologists. None of the responses suggested a refusal motivated by distrust or avoidance of research participation per se. This further supports the interpretation that these patients' refusals were app-specific rather than reflecting a general reluctance to engage in studies. This analysis allowed for the combination of basic categories into 5 overarching categories, providing a comprehensive understanding of the patients' perspectives and motivations for refusal: (1) Focus on Life Outside the Disease, (2) Focus on Disease and Treatment, (3) use of a Denial Mechanism in relation to content related to illness and treatment, (4) Technical Issues, and (5) Other Reasons. The process of categorizing responses with examples of patients' statements is provided in Table S1 in Multimedia Appendix 1.

The distress thermometer, a self-report measure of psychological distress, with an 11-point range from "no distress" (0) to "extreme distress" (10), resembling a thermometer [22,23], was used. Respondents were instructed to circle the number (0 - 10) that best describes their level of distress on the day of measurement. The validated Polish version was used; according to the validation results, a threshold of 5 points provides the greatest balance of sensitivity and specificity in selecting patients with severe distress.

The General Self-Efficacy Scale (GSES) by Schwarzer [24] was used to evaluate Self-efficacy beliefs. Self-efficacy is defined as the ability or level of confidence in performing

XSL•FO
RenderX

specific behaviors. The GSES consists of 10 questions, rated on a 4-point Likert scale ranging from 1 (“strongly disagree”) to 4 (“strongly agree”). The total score ranges from 10 to 40 points, with higher scores indicating a stronger sense of self-efficacy. Raw scores can be converted into standardized sten scores. The scale has demonstrated good reliability and measurement validity. The GSES has been translated into Polish by Juczyński [24].

The Ten-Item Personality Inventory (TIPI), a concise tool designed to evaluate the 5-factor personality model established by Costa and McCrae, was applied in the study [25]. TIPI was specifically developed to offer a brief (1 minute) assessment option in situations where using more comprehensive instruments would be unfeasible. The model encompasses Extraversion, Agreeableness, Conscientiousness, Emotional stability (or Neuroticism), and Openness to Experiences (10 items with five 2-item subscales). Respondents assigned a Likert score where 1 indicates “disagree strongly,” and 7 indicates “agree strongly,” with raw scores transformed into standardized sten scores. Correlations between the Polish version of TIPI and NEO-FFI confirm the convergent and discriminant validity of TIPI.

The Coping Orientation to Problems Experienced Questionnaire (Mini-COPE) was used to assess stress coping. The Mini-COPE, developed by Carver et al [26] and adapted into Polish by Juczyński and Ogińska-Bulik [27], comprises 28 items with 4 possible responses: “I haven’t been doing this at all” (0 points), “A little bit” (1 point), “A medium amount” (2 points), and “I’ve been doing this a lot” (3 points). Two items constitute one strategy, resulting in a total of 14 stress-coping strategies divided into 4 factors: Active Coping (comprising 3 strategies: Active Coping, Planning, and Positive Reinterpretation); Seeking Support (comprising 2 strategies: Seeking Emotional Support and Seeking Instrumental Support); Helplessness (comprising 3 strategies: Psychoactive Substance Use, Restraint, and Self-Blame); Avoidant Coping (comprising 3 strategies: Dealing with something else, Denial, and Venting). In addition, there are 3 strategies not belonging to any of the above-mentioned factors: Religion, Acceptance, and Humor. All strategies can be categorized into Active (effective) strategies and passive (ineffective) strategies. Active strategies include Active Coping, Seeking Support, Religion, Acceptance, and Humor, while passive strategies encompass Helplessness and Avoidant Coping. The questionnaire’s split-half reliability was 0.86, and the internal consistency for most scales was assessed as satisfactory.

Statistical Analysis

Categorical variables were summarized as frequencies and percentages. Continuous data were summarized as median values with IQR 25%-75%. For continuous variables, comparisons between more than 2 groups were performed by the Kruskal-Wallis H test and post hoc Dunn test with Benjamini-Hochberg *P* value correction. The Spearman correlation coefficient was assessed to examine correlations between variables. The classification of correlations used to evaluate the analyzed results was as follows: $0.0 \leq |r| < 0.1$ negligible correlation; $0.1 \leq |r| \leq 0.39$, weak correlation; $0.4 \leq |r| \leq 0.69$, moderate correlation; $0.7 \leq |r| \leq 0.89$, strong correlation; and $0.9 \leq r \leq 1$, very strong correlation [28]. Hierarchical clustering was based on Euclidean distance. Colors were scaled per column. A 2-sided $P<.05$ was considered statistically significant. Computations were performed in the R environment for statistical computing (version 4.0.1; R Foundation for Statistical Computing), released on June 6, 2020 [29].

Ethical Considerations

The study was approved by the Ethics Committee of the Maria Sklodowska-Curie National Research Institute of Oncology, Gliwice Branch (approval number KB/430-66/23). All procedures involving human participants were conducted in accordance with applicable ethical standards. Informed consent was obtained from all participants. Participant data were anonymized before analysis, and all personal information was handled confidentially in accordance with institutional data protection policies. No compensation was provided to participants for their involvement in the study.

Results

Participants

In the study group (N=56), all patients were diagnosed with primary early breast cancer (primary epithelial malignant tumors of the breast, at clinical stages I–III, eligible for treatment with curative intent, and with an Eastern Cooperative Oncology Group performance status of ≤2). The time since diagnosis ranged from 4 to 11 months, with most of the women undergoing preoperative systemic treatment (34/56, 60%). The age range was 32 - 67 years, with a mean age of 50 (SD 9) years. The majority of patients were married (40/56, 71%) and had at least one child (50/56, 89%). Demographic and clinical data are provided in Table 1.

XSL•FO
RenderX

Table . Sociodemographic and clinical characteristics of patients with primary breast cancer who refused to test the mobile psycho-oncology app within the clinical trial, Gliwice, Poland (2022 - 2023; N=56).

Characteristic	Value, n (%)	Value, mean (SD)	Value, median (IQR)
Age (years)	—[a]	50 (9)	48 (44-57)
Relationship status			
Married	40 (71)	—[a]	—[a]
Single	6 (11)	—[a]	—[a]
Divorced	7 (12)	—[a]	—[a]
Widowed	3 (5)	—[a]	—[a]
Children			
Yes	50 (89)	—[a]	—[a]
No	6 (11)	—[a]	—[a]

During preoperative systemic treatment	35 (64)	—[a]	—[a]
After systemic therapy	20 (37)	—[a]	—[a]

[a]Not applicable.

Reasons for Refusal to Participate in Testing the App

A total of 138 women were offered participation in a clinical trial testing a psycho-oncology mobile app. Of these, 70 (51%) patients declined to use the app and were subsequently invited to participate in this observational study, and 56 of these 70 patients (40.1%, 56/138) agreed to participate in this study and provided open-ended responses regarding their reasons for refusing the intervention. As detailed in the “Methods” section, the responses were coded and grouped into categories. The most frequently given reason was lack of time due to numerous medical appointments and examinations related to cancer diagnosis and treatment (13/56, 23%). The second most frequent answer (8/56, 14%) was lack of mental need or mental well-being. Other reasons included poor physical and mental well-being (7/56, 13%), reluctance to recall content related to illness (7/56, 13%), lack of time due to difficult family situation (6/56, 11%), reluctance toward new technologies (5/56, 9%), lack of time due to caring for a young child (4/56, 7%), lack of time due to demanding professional work (3/56, 5%), and lack of private telephone (2/56, 4%). One patient (1/56, 2%) had been in psychotherapeutic contact for many years and found it sufficient support for psycho-oncological issues as well. An analysis of the answers given by 2 independent psychologists working independently of each other made it possible to combine the above 10 answers into 5 main categories, of which the most numerous was “Focus on Disease and Treatment” (20/56, 36%). Less common were the reasons associated with denial mechanisms in relation to content associated with illness and treatment (15/56, 27%), life outside the disease (13/56, 23%), Technical Issues (7/56, 13%), and Other Reasons (1/56, 2%) (Table 2).

Psychological Outcomes

There were no missing values in the psychological assessments. The mean score in the patients' stress level measured with the distress thermometer was 5.0 (SD 2.1). The average level of distress in the whole group was moderate, close to the cut-off point according to Polish standards [23]. When analyzing the distribution of scores, we found that 63% of patients exceeded the cut-off point and 26% had a score of 7 or higher, indicating a significant escalation of distress. This means that at least a quarter of the patients in our study indicated a clinically significant escalation of distress. The mean score of generalized Self-efficacy measured with GSES was 32.1 (SD 5; stens: means 7.4, SD 1.9). Analysis of the 5 dimensions of personality measured using the TIPI questionnaire in patients refusing psycho-oncological eHealth support indicated the highest scores in the Conscientiousness dimension (mean 6.4, SD 0.9). The lowest score was obtained in the Neuroticism dimension (mean 3.4, SD 1.8). Mean scores for other personality traits were average: Extraversion (mean 5.8, SD 1.6), Agreeableness (mean 6.5, SD 0.8), and Openness to Experiences (mean 4.4, SD 1.5) (Table 3).

Table . Results of participants' stress level (distress thermometer [DT]), Generalized Self-Efficacy Scale (GSES), and personality trait characteristic (Ten-Item Personality Inventory [TIPI]) among patients with primary breast cancer who declined participation in the mobile psycho-oncology app clinical trial, Gliwice, Poland (2022 - 2023; N=56).

Questionnaire and variable	Value, mean (SD)	Value, median (IQR)
DT[a]		
Level of stress	5.0 (2.1)	5.0 (3.0-6.8)
TIPI[b]		
Extraversion	5.8 (1.6)	6.5 (5.4-7.0)
Agreeableness	6.5 (0.8)	6.8 (6.4-7.0)
Conscientiousness	6.4 (0.9)	7.0 (6.0-7.0)
Neuroticism	3.4 (1.8)	3.0 (2.0-4.5)
Openness to experience	4.4 (1.5)	4.5 (4.0-5.5)
GSES[c]		
Self-efficacy	32.1 (5.1)	32.5 (29.0-36.0)
Stens	7.4 (1.9)	7.5 (6.0-9.0)

[a]DT: distress thermometer.

[b]TIPI: Ten-Item Personality Inventory.

[c]GSES: General Self-Efficacy Scale.

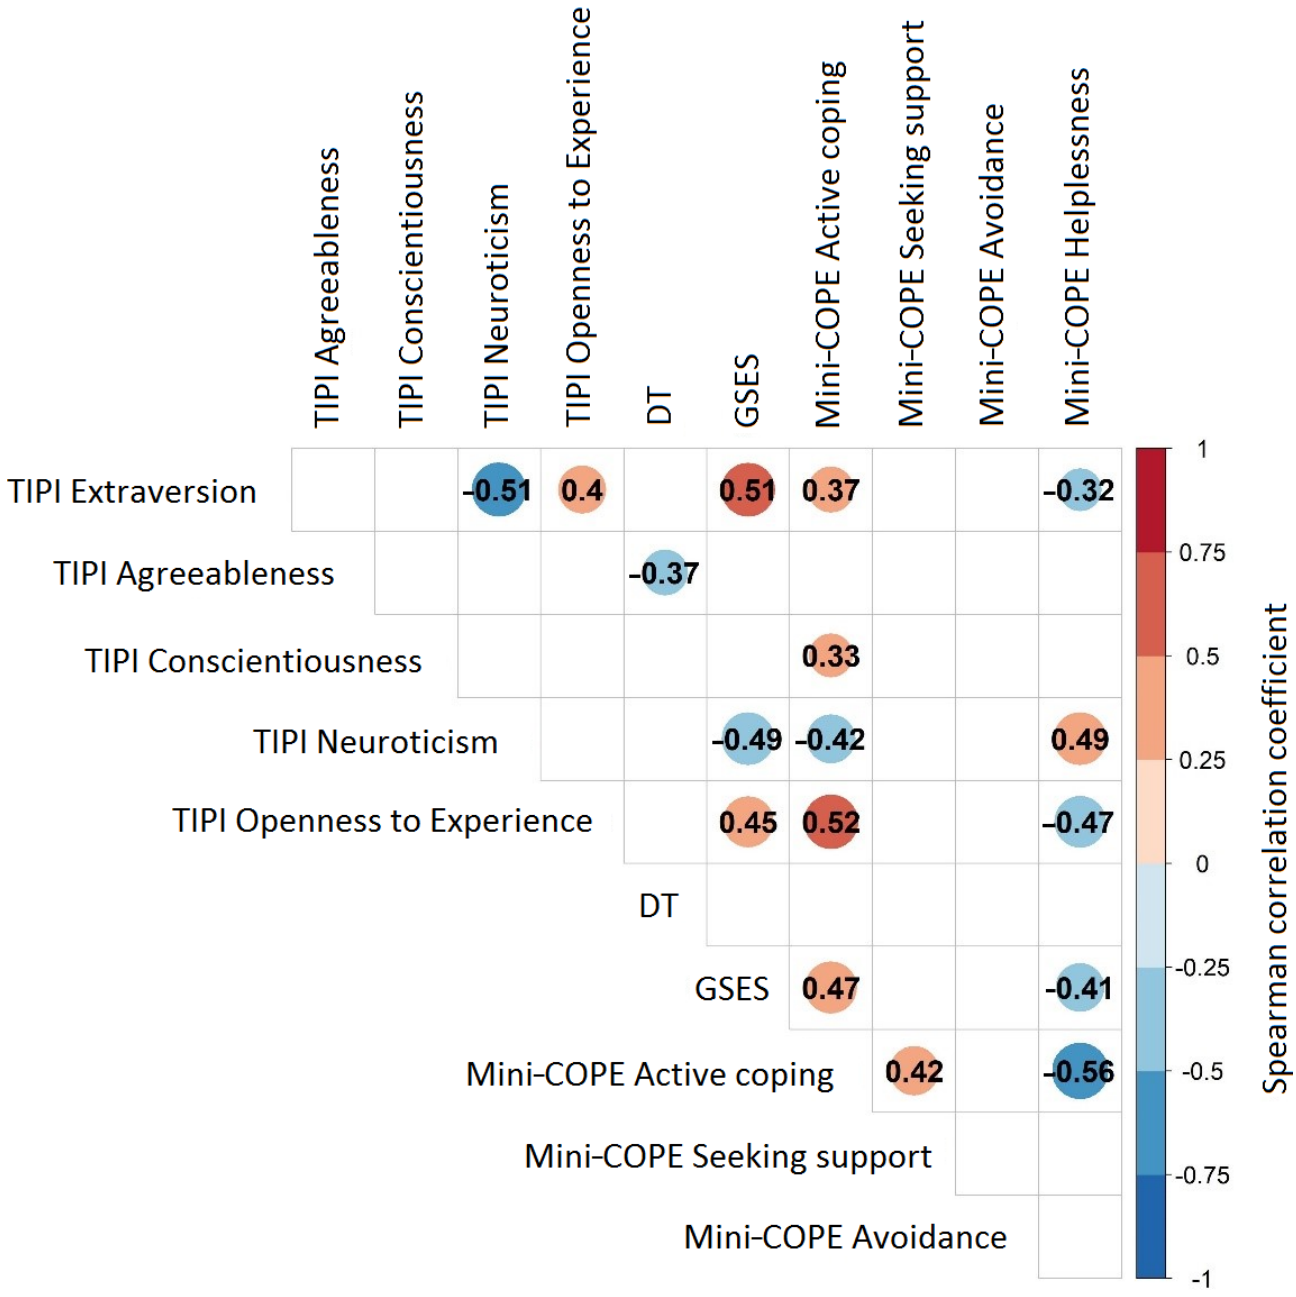
The results in the Mini-COPE showed that patients most often used the strategies of Active Coping (mean 2.6, SD 0.5), Acceptance (mean 2.6, SD 0.6), and Seeking Emotional Support (mean 2.6, SD 0.6). Also relatively common were the strategies of Planning (mean 2.4, SD 0.6), Positive Reinterpretation (mean 2.3, SD 0.7), Seeking Instrumental Support (mean 2.2, SD 0.8), and Dealing with something else (mean 2.1, SD 0.8). The least used strategies were Psychoactive Substance Use (mean 0.2, SD 0.6), Restraint (mean 0.5, SD 0.7), and Sense of humor (mean 0.8, SD 0.7) (Table 4).

Table . Coping strategies (Coping Orientation to Problems Experienced Questionnaire [Mini-COPE]) among patients with primary breast cancer who declined to test the mobile psycho-oncology app within the clinical trial, Gliwice, Poland (2022 - 2023; N=56).

Type, dimension, and name of stress coping strategies	Value, mean (SD)	Value, median (IQR)
Active strategies mean 2.1 (SD 0.94); median 2.5 (IQR 1.5-3.0)		
Active coping	2.4 (0.65)	2.5 (2.0-3.0)
Active coping	2.6 (0.5)	3.0 (2.5-3.0)
Planning	2.4 (0.6)	2.5 (2.0-3.0)
Positive reinterpretation	2.3 (0.7)	2.5 (1.5-3.0)
Acceptance	2.6 (0.6)	3.0 (2.5-3.0)
Sense of humor	0.8 (0.7)	1.0 (0.0-1.5)
Turning to religion	1.6 (1.2)	2.0 (0.5-3.0)
Seeking support	2.4 (0.72)	2.5 (2.0-3.0)
Seeking emotional support	2.6 (0.6)	3.0 (2.0-3.0)
Seeking instrumental support	2.2 (0.8)	2.5 (1.5-3.0)
Passive strategies mean 1.1 (SD 1.0); median 1 (IQR 0.0-2.0)		
Avoidance	1.5 (0.93)	1.5 (1.0-2.0)
Dealing with something else	2.1 (0.8)	2.0 (1.5-3.0)
Denial	1.0 (0.9)	1.0 (0.0-1.5)
Venting	1.5 (0.8)	1.5 (1.0-2.0)
Helplessness	0.6 (0.86)	0.0 (0.0-1.0)
Psychoactive substance use	0.2 (0.6)	0.0 (0.0-0.0)
Restraint	0.5 (0.7)	0.0 (0.0-1.0)
Self-blame	1.1 (1.0)	1.0 (0.0-2.0)



In the next step, correlations between individual variables of psychoemotional functioning were analyzed to identify possible personality profiles of patients in our study who refused to test the eHealth app. We observed moderate positive correlations between Extraversion and Self-Efficacy (r=0.51; P<.001), Helplessness and Neuroticism (r=0.49; P<.001), Self-Efficacy and Active Coping (r=0.47; P<.001), Openness to Experience and Self-Efficacy (r=0.45; P=.001), and Active Coping and Seeking Support (r=0.42; P=.003), Openness to Experience and Extraversion (r=0.4; P=.005), and Extraversion and Neuroticism (r=0.51; P<.001, Extraversion and Self-Efficacy (r=0.51; P<.001). We observed moderate negative correlations between Helplessness and Active Coping (r=−0.56; P<.001), Openness to experience and Helplessness (r=−0.47; P<.001), Neuroticism and Active Coping (r=−0.42; P=.003), and Helplessness and Self-efficacy (r=−0.41; P=.004) (Figure 2).

Heatmaps with hierarchical clustering did not identify subgroups with a specific personality-functioning profile, which indicates the homogeneity of the refusing group (Figure S1 in Multimedia Appendix 1). However, if we divided the group into 4 basic refusal categories (Focus on Life Outside the Disease, Focus on Disease and Treatment, Denial Mechanism, and Technical Issues) and analyzed each psychological test separately, we observed that patients giving different reasons for refusal differed in the severity of Neuroticism, use of positive reevaluation, and Self-efficacy. Analyses showed differences in Neuroticism between the Focus on Life Outside the Disease and Focus on the disease and treatment groups (P=.02), with the Focus on Life Outside the Disease group showing lower levels of Neuroticism. A higher level of Positive Reinterpretation was observed in the Focus on Life Outside the Disease group than in the Technical Issues group (P=.05) (Tables S2 and S3 in Multimedia Appendix 1). The results showed that, compared to the Focus on Life Outside the Disease group, patients in 2 groups had lower levels of Self-efficacy: the Focus on the Disease and Treatment (P=.03) and Denial Reaction group (P=.03) (Tables S2 and S4 in Multimedia Appendix 1). When we divided the group into 3 age groups: <45, 46-60, and >60 years, the only difference was in the use of denial strategies (P=.004). The 46 - 60 age group used this strategy more often than the ≥60 group (P=.04) (Tables S5 and S6 in Multimedia Appendix 1). There were no other differences in

XSL•FO
RenderX

psychoemotional functioning variables between the age categories.

Figure 2. Spearman correlation coefficient between stress level (distress thermometer [DT]), Generalized Self-Efficacy Scale (GSES), personality trait characteristics (Ten-Item Personality Inventory [TIPI]), and stress coping strategies (Coping Orientation to Problems Experienced Questionnaire [Mini-COPE]) among patients with primary breast cancer who declined to use the mobile psycho-oncology app within the clinical trial, Gliwice, Poland (2022-2023). A blank space indicates an insignificant correlation ($P \geq .05$).

Discussion

Principal Findings

In our study, we primarily aimed to delineate the motivations and their associations with the psychoemotional functioning of patients with primary breast cancer who consciously declined the use of eHealth technology in the form of a mobile psycho-oncology app as part of a clinical trial. In line with this objective, we examined the reasons behind the refusal to participate in the clinical trial involving the app, as expressed by the patients in an open-ended question, and evaluated their psychoemotional functioning, encompassing stress levels, self-efficacy, personality traits, and coping strategies. Importantly, all psychological assessments and reasons for refusal were collected from patients who declined the app intervention as part of a clinical trial but agreed to participate in our separate observational study, indicating that their decision was app-specific rather than a general reluctance toward research involvement. In addition, we categorized patients based on their reasons for declining participation in the study and compared the psychoemotional functioning of patients within these groups.

XSL•FO
RenderX

Refusals to Participate in a Clinical Trial Using an eHealth App

The percentage of refusals in our group is significantly higher compared to other studies [30,31]. However, there are also studies in which the refusal percentage was even higher than in our study [11]. It should be stressed that the team carrying out the clinical research on the use of the tested eHealth app did not offer participation to all consecutive patients; this could be confirmed by the upper limit of age in the tested group of patients (67 years), significantly lower than the upper age limit for patients treated by preoperative therapy in Poland. In the eligibility criteria of the trial, the skill to use the electronic tool was one of the major requirements; thus, the refusal rate is calculated in the group of patients apparently able to use it.

As mentioned previously in the Introduction section, there are limited studies that examine the reasons for rejecting the use of eHealth solutions. Gupta et al [20] listed 4 obstacles to recruiting patients for a study using a cell phone app: (1) coordination with clinic staff, (2) perceived burden among patients with breast cancer, (3) limitations on technology adoption and use, and (4) availability of resources among study staff. The reasons given by our patients corresponded to the second challenge domain identified by Gupta et al [20]. The remaining domains were less visible in our study, which may be due to a different way of constructing the refusal categories in our study compared to that of Gupta et al [20]. Among other things, when comparing these categories, we included "Unfamiliarity with mobile apps" as a "technical issue," whereas Gupta et al [20] classified it as a "perceived burden" (2nd category). Most of the reasons for refusal cited by our patients are also commonly mentioned in other studies as reasons for withdrawal from technology-based interventions [30,31]. The only exception was "reluctance to recall disease-related content," which we did not find in other studies. Meanwhile, patients reporting a reluctance to recall disease-related content are an interesting group from a clinical perspective, as they may be more likely to use a denial response, which is a risk factor for underestimating disease symptoms despite the available information and their intellectual capacity to comprehend it [32,33]. da Silva et al [34] demonstrated that patients with breast cancer made excuses to avoid check-ups, refrained from touching their breasts, and even avoided using the word "cancer." It is noteworthy that in our study, patients declaring reluctance to recall content related to illness as a reason for not using the app exhibited higher levels of Neuroticism.

It would be important to consider whether reluctance to use the app was derived from reluctance to participate in the clinical trial. However, none of the patients mentioned such a reason in the open-ended question. At the same time, these patients agreed to participate in the observational study presented in this paper, which was conducted after their refusal to test the mobile app, suggesting that it was not the mere fact of "participating in the study" that was a deterrent, but the topic itself, that is, testing the phone app.

Psychoemotional Functioning of Patients With Breast Cancer Who Declined the Use of eHealth Apps

Analysis of the results indicates that the level of stress among the patients does not appear to be the main reason for refusing to use the psycho-oncology app. Patients who declined participation may still have experienced moderate stress; however, this was not a decisive factor in their decision. This finding suggests that the refusal was more likely related to individual preferences, perceived usefulness of the app, or other psychomotor factors, rather than to low stress levels. It appears that patients who declined participation had a relatively high sense of Self-efficacy, consistent with previous Polish research [27]. It is plausible that the elevated Self-efficacy of our patients led them to forgo the use of the app, as they felt emotionally equipped to handle the challenges of illness. This conjecture aligns with Juczyński and Ogińska-Bulik's [27] assertion that heightened Self-efficacy influences an individual's positive assessment of personal resources in stressful circumstances. Moreover, the author contends that increased Self-efficacy is linked to engaging in health-related activities, a conclusion supported by other researchers [35,36]. However, the latter was contradicted by the results of our study, as our patients declined app usage despite possessing high Self-efficacy. This may be connected with the fact that their decision was more related to perceptions of the app itself than to a general disengagement from health-related behaviors or research. It is possible that they did not view app usage as a health-enhancing activity; this stresses the necessity of addressing this group both in the design of interventions and in the channels of their delivery at decisive moments.

In terms of coping with stress, patients most frequently used the strategies of Active Coping, Acceptance, and Seeking Emotional Support, and least frequently used the strategies of Psychoactive Substance Use and Restraint. This is a recurrent pattern of the most and least frequently used strategies in other Polish studies [37] by the authors of the test, which are considered to be highly effective in coping with stress.

Among personality dimensions, Neuroticism and Openness to Experience were relatively lower, which may help explain patients' reluctance to use the eHealth app. Openness to Experience is conceptualized as a willingness to accept novelty in life, including new ideas and concepts [25]. Thus, the lower Openness to Experience score of our patients may indicate a lack of readiness to accept the app as something new and unfamiliar. In addition, the low Neuroticism levels of our female patients may have been a protective factor against heightened negative emotions, thereby reducing motivation to seek psychological help. It should be noted, however, that the scores on these 2 personality dimensions, although the lowest, were within Polish normative values.

Psychoemotional Functioning in Relation to the Reasons for Refusal to Participate in the Study

Differences in the psychoemotional functioning of patients were observed based on the stated reason for refusal to participate in the study. Patients who cited focusing on life outside the disease as the reason for refusal exhibited lower levels of Neuroticism, more frequent use of positive reevaluation, and higher levels of

XSL•FO
RenderX

Self-efficacy than patients giving other reasons for declining the app intervention. These psychoemotional characteristics suggest better coping with the illness and treatment situation. Lower Neuroticism is associated with a reduced tendency to experience anxiety and sadness, greater emotional balance [25], and the ability to positively reinterpret events, leading to experiencing positive emotions despite the challenges [27]. High Self-efficacy is linked to greater self-confidence and more effective action [24]. This indicates that patients who felt too focused on their life outside the disease to participate in testing the psycho-oncology app were unlikely to require additional psychological support related to a cancer diagnosis. However, 3 other groups were identified: the "Denial Reaction" group had lower levels of Self-efficacy, the group citing technical difficulties as a reason for refusal was less likely to use the positive reappraisal technique, and the group focused on the disease and treatment had lower levels of Self-efficacy and higher levels of Neuroticism. Overall, the study group tended not to exhibit significantly elevated levels of stress and tended to have high levels of Self-efficacy. The aforementioned 3 groups of patients could potentially have needed additional psycho-oncological support that the app could have provided but did not make use of it.

Clinical Implications

Our research shows that when exploring the reasons behind patients' reluctance to use eHealth solutions, the refusing group should not be considered uniform. Our patients provided various reasons for their refusal to use a psycho-oncology mobile app, and their psychoemotional functioning differed depending on the reason. The aforementioned 3 groups of patients could have potentially benefited from using the psycho-oncological app, but the standard procedure of inviting them to use the app (direct contact by a nurse during routine pretreatment visit) did not effectively persuade them. When implementing eHealth solutions for routine psycho-oncological support of patients with breast cancer, it is essential to understand the reasons for patients' refusal to engage with such interventions, as this enables the use of more personalized incentives. Similar recommendations have been made for patients refusing to participate in clinical trials [38]. In addition, we recommend screening for psychoemotional functioning in patients with breast cancer before they are offered support in the form of an eHealth intervention. Such screening allows, first, the identification of patients who do not need additional support and, second, the presentation of screening results to patients as a personalized prompt (eg, indicating that the use of denial mechanisms or low self-efficacy potentially makes them more emotionally vulnerable during treatment, which they can effectively counteract with the support of the mobile app).

The most crucial issue is the problem of refusal rate in the context of eHealth interventions. Increasing the approval rate for novel tools is essential for understanding their population-level impact; possibly, the idea of carrying on the trial on both patients agreeing to use the tool and those refusing but who agreed to participate in this observational study would lead to the most reliable results of investigations. Nevertheless, we deliberately chose to focus this paper solely on the latter group. Our primary aim was to explore and categorize the reasons for refusing to use the eHealth app—a topic that, to our knowledge, has not yet been systematically addressed in the literature. Including comparative data at this stage might obscure the clarity of our categorization and shift the focus away from our core research objective. We acknowledge the importance of such a comparison and have collected data from users of the app; we intend to publish a separate article presenting a detailed comparison between users and nonusers. In addition, including these data here would significantly increase the length and complexity of this paper. We would like to draw attention again to the lack of standardized tools for investigating patients' reasons for refusing to use psychological eHealth tools [18]. The procedure we used to categorize patients' reasons for refusal was due to the lack of these tools. Importantly, the refusal we examined in this study pertained specifically to the use of the eHealth app, not to participation in clinical research more broadly. The results of our study, showing the different psychoemotional functioning of patients depending on the reason for refusal, indicate that this procedure was accurate and valid. We hope that this way of analyzing the reasons for patients' refusal to use psychological eHealth tools will be developed in further studies.

Moreover, our review of the literature revealed that the research tools we used are not commonly used. However, in our opinion, they are valuable and reliable as a standard data source of diagnostic information, especially considering the relatively short time required for patients to complete them. We therefore recommend these tools for psychological screening of patients with breast cancer.

Study Limitations

In our study, we used a small sample of a relatively homogeneous group of patients in a single breast cancer center. The generalizability to more diverse populations, patients in other geographic areas, or centers with different practices should be tested in the future. Poland is a country with a relatively homogeneous population of Caucasians, and in further studies, we will consider broader collaboration to increase diversity among participants.

In addition, although the intervention is briefly described as a psycho-oncology mobile app, we acknowledge the need for a more detailed presentation of its content, functionality, and interactivity. This information will be provided in a separate publication specifically dedicated to the intervention's development and implementation.

We also recognize that health care infrastructure and digital health literacy vary across countries. As such, the generalizability of our findings may be limited in settings with different eHealth accessibility or patient attitudes toward digital care. While our findings may not directly generalize to countries with highly advanced digital health systems, we believe they are especially relevant for regions where psychological eHealth solutions are still emerging and face similar adoption barriers.

We acknowledge the potential impact of self-selection bias. Our participants represent a specific subset of patients who refused to use the app but agreed to participate in the observational study. Their willingness to engage in research, despite refusing

XSL•FO
RenderX

the app intervention, may indicate characteristics that differentiate them from patients who declined both. This bias should be considered when interpreting the findings. A comparative analysis involving patients who used the app is currently in preparation and will be presented in a separate paper.

Despite these limitations, we believe that this study enriches our knowledge of the psychoemotional functioning of patients with breast cancer who refuse to use psychological eHealth tools in the form of a mobile app and their reasons for declining the app-based intervention, rather than research participation in general.

As a broader contextual note, the attitude of citizens in various countries to adopt novel solutions, especially in the technological domain, plays a key role. According to the latest Eurostat report [39], Poland is significantly below the European average in terms of technological expenditures and dissemination. However, numerous eServices are operational, including public health eServices, and the general enthusiasm for the use of various simple digital services (with ePayments at the forefront) is significant. For example, in 1 study designed by Finnish and Polish researchers, children were offered a mobile app intervention; Polish parents agreed in 92% of cases, while Finnish parents agreed in 56% [40], even though Finland rates significantly higher than Poland on the majority of Eurostat measures of technological enthusiasm. Seventy percent of Polish adults accept using web-based services for health-related issues [41], and this percentage is comparable to the level of Acceptance observed in our study. Thus, we consider our results potentially generalizable to a wider European population in countries with significant barriers to the adoption of psychological eHealth tools.

Conclusions

When incorporating eHealth solutions into the regular psycho-oncological support for patients with breast cancer, it is crucial to understand the reasons behind their refusal to use such solutions. In addition, it is important to consider these reasons in the context of the patients' psychoemotional well-being. This understanding allows for the implementation of more personalized incentives for those who could benefit from eHealth but are hesitant to use it. To achieve this, we recommend screening the patients' psychoemotional functioning.

Acknowledgments

The authors would like to thank the patients who generously agreed to participate in the observational study. We also thank the clinical staff at the Maria Sklodowska-Curie National Research Institute of Oncology, Gliwice Branch, for their assistance with data collection. ChatGPT (OpenAI) was used only for language refinement and formatting assistance. All content, study design, data interpretation, and conclusions were developed by the authors.

Abstract

Background: Mobile health (mHealth) interventions show promise in supporting tobacco cessation. However, Black adults who use tobacco products are not well represented in mHealth studies for tobacco cessation, and their preferred features of mHealth apps are not well known. Identifying types of mHealth app features for tobacco cessation preferred by Black adults is critical to developing a culturally adapted app, with increased uptake by the target population.

Objective: The goal of this study was to explore culturally relevant preferences for features of smoking cessation mHealth apps among Black adults who use tobacco products.

Methods: A comprehensive list of features of mHealth apps for tobacco cessation was developed based on previous research and a review of existing mHealth literature. Through a content analysis, this list was divided into subgroups and used to develop a focus group guide. We recruited participants from Instagram, a social media platform. Eligible focus group participants included people who reported current use of a tobacco product, identified as being African American or Black, were 21 years old or older, and had access to Wi-Fi or the internet. Participants had to indicate interest in the use of an mHealth app for tobacco cessation. Participants discussed their opinions about different app features, including what features they felt would increase the use of an app by Black adults. Recordings from the focus groups were transcribed and coded deductively and inductively. We conducted a thematic content analysis of the resulting transcripts.

Results: Forty adults aged 21 - 69 (mean 43, SD 13.6) years participated in 8 focus groups. Fifty-seven percent were female, and 88% endorsed current cigarette use. Four central themes that represented app features emerged. (1) Participants wanted representation and inclusivity through personalization and featuring people with similar lived experiences, including representative images and relevant health information. (2) Participants desired the app to feature a diversity of experiences such as testimonials from individuals from different backgrounds rather than solely focusing on racial identity or excessive targeting of the Black community. (3) Participants desired accountability through trusted connections with health care professionals and other support groups within the app, as well as app tracking capability. (4) Encouragement and motivation were more salient incentives than monetary rewards.

Conclusions: Black adults who use tobacco products prefer a tobacco cessation app with features that are inclusive, relatable, supportive, and motivating. These findings can serve as the groundwork for the development of an mHealth app that will appeal to Black adults, potentially leading to increased app use, successful cessation, and health equity.

Introduction

In the United States, certain racial minorities, including Black adults, face a disproportionate burden of negative health effects from tobacco use [1]. Compared to other racial and ethnic groups, Black adults who use tobacco products are more likely to experience adverse health issues because of their tobacco use, such as coronary heart disease, and have a higher morbidity

XSL•FO
RenderX

and mortality rate from other tobacco-related health conditions [2,3]. For instance, compared with Whites, Black adults have a higher mortality rate from cancer (221 vs 186 per 100,000 population) [4]. Despite starting to smoke at an older age [5] and being more likely to make a quit attempt than any other racial group, Black adults who use tobacco products are less likely to successfully quit than other racial groups [6]. Black adults also have lower odds of both quitting and using Food and Drug Administration cessation medications, despite having greater odds of using behavioral counseling/self-help materials [7].

Novel interventions, such as mobile health (mHealth) interventions, show promise in supporting tobacco cessation for Black adults. mHealth apps have previously been successfully used with Black adults to help manage conditions such as diabetes and obesity [8,9]. Compared to White adults, Black adults are more likely to use apps to inform their medical decisions [10]. mHealth apps can also increase access for Black adults who use tobacco products by reducing barriers to receiving care, like cost and transportation logistics [11,12]. One study examining willingness to participate in mHealth app research for weight management among Black women found high receptivity, frequent smartphone usage, and existing use of smartphones to access information on health and wellness, suggesting mHealth apps could be used to empower and promote participation [13].

Although a promising route to increase tobacco cessation, mHealth apps should be culturally adapted to address unique factors that impact Black adults who use tobacco products. Black adults use menthol products and smoke cigars at higher rates [14], smoke fewer cigarettes per day [15], and may be more likely to use tobacco products as a result of stress related to racial harassment [16]. One study examining differences in addiction and quitting experiences concluded that these differences may suggest that Black adults who use tobacco products experience a different “quitting process” [15] as compared to White smokers. However, Black adults who use tobacco have not been well represented in prior mHealth studies for tobacco cessation, and their preferred features of mHealth apps are not well known. In addition, research has shown that tailoring interventions in ways that incorporate values and cultural experiences for patients, especially patients from minority backgrounds, can increase engagement with the intervention [17]. For example, visual representation of an individual’s culture in an intervention, delivery or promotion of an intervention by an individual from the target population, or the use of language that the target audience can relate to can enhance the appeal of that intervention [17,18]. A critical step to developing a tobacco cessation mHealth app that Black adults are receptive to and are likely to use is to identify desirable app features.

Furthermore, the extent to which preferred features satisfy key components of the self-determination theory is also important. According to the self-determination theory, autonomy, competence, and relatedness are key factors necessary for intrinsic motivation as well as maintenance of behavior change [19]. Autonomy, described as the intrinsic need to regulate one’s own behavior without the influence of external factors, has been found to be effective in tobacco cessation [20]. Competence, also described as the need for an individual to feel confident and capable as it relates to behavior change, can be supported by app features such as an app’s ability to provide information about tobacco cessation or provision of information about a user’s progress or behavior [21]. Relatedness is described as connecting with others and can be achieved by an app that allows for social support or interaction with others [21]. Each component of the self-determination theory plays an important role in cessation-related behavior [20,22]. The goal of this study was to identify features of mHealth apps for tobacco cessation that Black adults who use tobacco products would like to see in an app and what features will make the app more inclusive [19-22].

Methods

Study Design

Between June and July of 2023, we conducted 8 focus groups with 40 Black adults who use tobacco products. Participants were recruited using the social media platform Instagram. After completing a brief screener and obtaining consent during a brief screening call, eligible participants were purposively invited to participate in focus groups. Focus groups were stratified by age groups (21 - 34, 35 - 54, and ≥55 years old) to optimize representation.

Participants

Eligible participants included Black adults who were 21 years old or older, who reported current use of one or more tobacco products in the past 30 days, spoke English, and were current US residents at the time of recruitment. Exclusion criteria included lack of access to the internet and lack of interest in the use of technology for smoking cessation.

Focus Group Guide Development

To identify which features to discuss during focus groups, we developed a comprehensive list of features of mHealth apps for tobacco cessation using previous research and a review of existing mHealth literature [23-31]. The mHealth apps involved were designed based on behavior change techniques and theories, such as the principles of acceptance and commitment therapy [24,26], persuasive technology for behavior change [27], or followed the US clinical practice guidelines [28,31]. One of the apps was developed by the National Cancer Institute [28], and another was developed to target young adults who are motivated to quit [27]. We then divided this list into different domains to explore with participants. Initial mHealth app feature domains included content, user experience, personalization, tracking, privacy and security, connections or support, and inclusivity. Within each domain, several features were included to discuss with participants, with the primary focus being whether these features were inclusive and preferred by Black adults who use tobacco products. Using guidance from experts, the resulting domains and features were organized and distilled. The list and resulting domains were further refined through focus groups using the focus group guide.

XSL•FO
RenderX

Focus Group Procedures

Using the list of domains and features of mHealth apps, the research team developed the focus group guide to address the research question: What features in mHealth apps for tobacco cessation are preferred by Black adults? The interview guide included questions and probes about participants' experience with tobacco use and cessation, and experience with mHealth apps. Next, the guide listed each of the domains and features with a corresponding question about what features they preferred and a final question to get feedback about other design features or advice participants had. The semistructured focus groups were conducted using Zoom videoconferencing software to allow for participation from different locations within the United States, and each focus group lasted an hour [32].

Analysis

The resulting focus group recordings were professionally transcribed, and transcripts were uploaded into Atlas.ti, a qualitative data analysis software (version 23). Using the focus group guide, an initial codebook was developed. The qualitative analysis team comprised 3 researchers (CE, SAC, and RP), who each had prior experience with qualitative coding and received formal qualitative and mixed methods training at the University of North Carolina at Chapel Hill. After familiarizing themselves with the codebook, 2 researchers (SAC and RP) independently coded a randomly selected transcript with the guidance of the senior researcher (CE). To establish the rigor of the analysis, we applied multiple methods to strengthen the credibility, dependability, and confirmability. First, we documented codebook revisions and applied analytic triangulation with multiple coders who reviewed transcripts independently and participated in consensus meetings to review discrepancies, add new codes, and refine definitions as needed. To assess interrater reliability, Krippendorff α was used, and the initial interrater reliability was calculated to be 0.769, indicating substantial agreement. After resolving coding conflicts, a different transcript was then coded, and "near perfect" agreement, 0.9, was reached. Upon reaching this threshold of high agreement, the team recoded the initial transcript and coded the remaining transcripts with the finalized codebook.

Furthermore, the focus groups were conducted with cultural sensitivity. For instance, the main facilitator of the focus groups was a member of the research team and is also a part of the Black community, as well as familiar with participants' cultural values [32]. We did not conduct member check-in to reduce the burden on participants and concerns for confidentiality. However, the data were presented to the larger research team, and findings were discussed in detail [33].

Using thematic content analysis, the research team discussed and identified recurring themes and concepts across the transcripts [34]. The team determined that thematic saturation was achieved after the completion of 8 focus groups [35].

Ethical Considerations

This study was approved by the institutional review board at the University of North Carolina at Chapel Hill (24 - 0798). All study participants were informed about the study aims and significance, as well as the methods. Participants gave their informed consent, retained the rights to withdraw from the study at any time, and were informed of the confidentiality and anonymity of the data and the goal to publish findings from the study. All participants received a US $50 gift card for their participation in the study.

Results

Sociodemographic and Tobacco Use Data

Forty adults aged 21-69 years, with an average age of 43 (SD 13.6) years, participated in 8 focus groups (Table 1). Most participants were female, and the majority were non-Hispanic. Many participants endorsed current cigarette use. Fifty-five percent (n=22) reported use of electronic cigarettes or other vaping devices, while 40% (n=16) endorsed use of cigars.

XSL•FO
RenderX

Table . Demographics and tobacco use characteristics of participants (N=40).

Characteristics	Value
Age (years), mean (SD)	43 (13.6)
Sex (female), n (%)	23 (57)
Race, n (%)	
Black/African American	36 (90)
Black/African American and some other race, ethnicity, or origin	4 (10)
Ethnicity (non-Hispanic), n (%)	37 (92)
Sexual orientation, n (%)	
Straight	33 (82)
Gay or lesbian	2 (5)
Bisexual	5 (13)
Current cigarette use, n (%)	
Yes	35 (88)
Current other tobacco product use, n (%)	
Yes	31 (78)
Electronic cigarettes, e-cigarettes, or other vaping devices	22 (55)
Cigars, for example, little cigars, cigarillos, or large cigars	16 (40)
Smokeless tobacco, for example, chewing tobacco, snuff, or snus	6 (15)
Water-pipe tobacco or hookah	5 (13)
Other types of oral nicotine products, such as Velo lozenges, Rogue tablets, Lucy gum, or Pixotine toothpicks	1 (3)
Other	3 (8)
None of the above	9 (23)

Four central themes emerged about what mHealth app features were desirable by Black adults who use tobacco products. Each theme had 2 - 3 subthemes that represented different domains of mHealth app features. See Table 2.

Table . Themes and subthemes with domains of mobile health app features represented.

Themes	Subthemes	Domain of app feature
Participants wanted representation and inclusivity through personalization and featuring people with similar lived experiences	• Inclusion of images to represent the target population • Personalization of the app • Inclusion of content about relevant health risks	• Representation and inclusivity • User experience • Content and inclusivity
Excessive targeting of the Black community was unappealing, and participants desired the app to feature a diversity of experiences rather than solely focusing on racial identity	• Inclusion of testimonials from people with different backgrounds • Outreach in the Black community	• Content • Social support
Participants desired accountability through trusted connections, and app tracking capability	• Connection with health professionals • Supportive anonymous community within the app • App tracking capability	• Professional support • Social or peer support • Tracking/user experience
Encouragement and motivation were more salient incentives than monetary rewards	• Nonmonetary rewards • Provision for diverse reward options	• Gamification and rewards

XSL•FO
RenderX

Theme 1: Participants Wanted Representation and Inclusivity Through Personalization and Featuring People With Similar Lived Experiences

Content and Inclusivity: Inclusion of Images to Represent the Target Population

When asked how to make the app more inclusive of Black adults, several participants emphasized the need to create an app that features Black adults.

> *If we get on the app and we see a lot of us, then that will make us wanna use it more.* [Focus group 1, Interviewee 1]

> *You gonna get more people who's like, "Hey, that applies to me. First of all, they look like me. They talk like me...They kinda think like me."* [Focus group 3, Interviewee 6]

One person lamented that it was not common to see themselves represented in existing apps.

> *You know, like I need to see people of color, you know..., connecting my eyes because it's not [in] a lot of apps out here...* [Focus group 6, Interviewee 2]

Testimonials from fellow Black individuals were seen as a way to make people want to use the app:

> *...having testimonials of other African-Americans, 'cause that would like make me at least feel more comfortable to even wanna try the app. Just seeing that other people that look like me have used it and have something positive to say.* [Focus group 4, Interviewee 3]

User Experience: Personalization of the App

Some believed that inclusivity could be achieved through personalization of tobacco use and cessation goals.

> *...[to] feel like you [are] talking to somebody that you know...maybe you could pick up from the personalized questions in beginning.* [Focus group 6, Interviewee 2]

Participants also believed personalization could be achieved through in-app customization, which can allow people to have their goals at the forefront.

> *...you should be able to customize [the app], you know, or personalize your experience with certain personal goals and..., based on your smoking habits...* [Focus group 4, Interviewee 2]

> *..Then this goal is set to be like the basis of the notification and the recommendations you receive.* [Focus group 4, Interviewee 2]

Content and Inclusivity: Inclusion of Content About Relevant Health Risks

The inclusion of content about their health risks as Black adults who use tobacco products was also suggested:

> *Include like the health aspect of it, like what smoking contributes to, like, just to add the statistics like, you know, African Americans,...make sure that you mention more of how it affects us as-as a culture.* [Focus group 7, Interviewee 5]

With personalized content, participants hope to find stories to relate to.

> *Personalize it because everyone has their own story. So, if you can find the testimonials that can represent you, that would work.* [Focus group 1, Interviewee 2]

Some indicated that having personalized content would be preferable because they have different experiences and different stressors.

> *...involve Black people [36], we have shared experiences that only [we] can understand...Like a Black mother or Black woman—if I need help, she could like advise me and pull me through.* [Focus group 4, Interviewee 4]

> *I think people that use cigarettes as a coping mechanism...I have—for example, stressors in the neighborhood...* [Focus group 3, Interviewee 2]

Theme 2: Excessive Targeting of the Black Community Was Unappealing, and Participants Desired the App to Feature a Diversity of Experiences Rather Than Solely Focusing on Racial Identity

Content: Inclusion of Testimonials From People With Different Backgrounds

While many participants voiced that the app should offer representation and inclusivity where Black adults are represented, many were adamant that the app should not focus on Black adults solely.

> *I don't wanna feel like it's directed right at me 'cause I'm Black. 'Cause I'm more than just Black.* [Focus group 2, Interviewee 2]

Rather, participants voiced that they wanted an inclusive app open to everyone struggling with smoking.

> *It should be point to everyone with smokes, despite religion, despite your-your race, despite whoever you are.* [Focus group 1, Interviewee 3]

> *...provide practical solutions accessible to users from various income levels. You know, regardless of-regardless of whether you Black or not.* [Focus group 4, Interviewee 2]

Participants suggested that one way to bring diversity into the app is to include testimonials from people from different backgrounds.

> *I would like to hear,...different people's testimonials...because we all have different stories, you know, and different reasons for doing the things that we do.* [Focus group 1, Interviewee 1]

Having the app feature real stories was viewed as a way to motivate app use:

> *...if you share like a real story of somebody that, you know, suffered bad consequences for smoking for not*

XSL•FO
RenderX

> *so long, that will probably motivate me to use the app.* [Focus group 7, Interviewee 7]

Social Support: Outreach in the Black Community

Finally, some participants suggested conducting outreach at events within the Black community to promote the app and collaborate with respected figures:

> *...have it displayed in a way that's attractive to us, and then also present it in the areas that we are...events that we go to.* [Focus group 6, Interviewee 4]

> *You need to get...somebody famous. I'mma just use Diana Ross just for name sake, right? Say she used to smoke. You get her to talk about it. We all know, in the African American community, word of mouth is the most powerful thing we have.* [Focus group 3, Interviewee 6]

Some participants suggested social media marketing:

> *...if I have like a good TikTok video of someone that's like a Black that's...reviewing or giving me something to pull me in, that's definitely gonna make me go and download it.* [Focus group 6, Interviewee 4]

Another participant reflected on their experience of trying an app because it was recommended by an influencer:

> *I actually got to know about it by...[a] Black female YouTuber and that's how I got interested...*
>
> *[Focus group 4, Interviewee 4]*

Theme 3: Participants Desired Accountability Through Trusted Connections and App Tracking Capability

Professional Support: Connection With Health Professionals

When asked whether the app should offer connections to other app users, doctors, or other health care providers, participants expressed their desire to connect in order to promote accountability. Some participants indicated talking to professionals would help keep them accountable to their goals, either by providing advice, "that would seem pretty nice to be able to...have a coach that, you know, that you can go to for advice or assistance..." [Focus group 1, Interviewee 1] or by monitoring their progress, "I think you should have some kind of feature that to share your usage with your physician and stuff like that or your coach" [Focus group 4, Interviewee 2].

Social Support: Supportive Anonymous Community Within the App

When asked about connections with other users of the app, most participants indicated interest in seeking supportive accountability within the app:

> *I think it will be better to have someone that, you know—'cause my friend doesn't smoke, so someone that understands. But to be able to hold you accountable.* [Focus group 1, Interviewee 1]

Participants expressed a desire to decrease loneliness by connecting with others who understand what they are going through:

> *I find that quitting smoking is like the loneliest thing I've ever dealt with in my life...[If] there's like a little message board type of thing inside the app where people can just write in,...what they're going through.* [Focus group 1, Interviewee 2]

Most participants preferred the community within the app to be anonymous and were interested in anonymous interactions through groups, games, and a leaderboard, "to kind of promote data security...the information of the user should be de-identified or...be on the app as anonymous user" [Focus group 4, Interviewee 2] and "...in terms of being able to see what might be called like a leaderboard or a scoreboard...it can kind of make it...a bit more interactive" [Focus group 7, Interviewee 3].

Although most participants wanted a quit buddy within the app, they did not want this quit buddy to be a family member or friend. A few people noted that friends and family can be triggers for smoking and they are not understanding, "because sometimes family and friends can be triggers to smoking" [Focus group 8, Interviewee 3] and "sometimes like she said, you can't really talk to family or friends about it, 'cause they don't—they don't do it 'cause they don't understand it..." [Focus group 1, Interviewee 1]. While most participants did not want their friends and family connected to the app, some expressed that it would be helpful to have them understand and provide accountability: "It'll give them an insight of what we're going through" [Focus group 8, Interviewee 1] and "I think it's a good idea to have, help because it could help you track your health and with how many smoking occurrences have you smoked per smoke a day, and can get your family involved and friends" [Focus group 8, Interviewee 7]. When asked if they wanted the app to connect with social media, some participants expressed fear of judgment and mean comments from other social network apps.

> *You know, there's some nasty comments, tellin' you to just get over it.* [Focus group 5, Interviewee 6]

> *I don't want that stuff flashed across Facebook and-and everybody to know what I'm tryin' to do or attemptin' to do because there's a lotta unnecessary opinions.* [Focus group 5, Interviewee 6]

Tracking and User Experience: App Tracking Capability

When asked about app tracking capabilities, most participants noted that they want to be able to track their usage to keep them accountable.

> *Say, I might smoke this many a day. How 'bout the next day—and-and-and a tracker that helps me keep accountability.* [Focus group 5, Interviewee 6]

A few participants noted that tracking their triggers through the app would allow them to learn what to avoid.

> *It help you identify your triggers, and you'll see,...what things cause you to smoke more so you could, like, lean away from it or stay from it,*

XSL•FO
RenderX

> *dependin' on what it is. So, I think it's [an] excellent idea.* [Focus group 3, Interviewee 6]

Some participants expressed a desire to have frequent notification reminders to support accountability.

> *So I need an app that's going to be a constant reminder, almost an annoyance, you know, and - and to help me.* [Focus group 8, Interviewee 2]

Most participants indicated that accountability could be supported through reminders of their goals.

> *The daily goals are there, the notifications are there to remind you of your goals and all, so, uh, that should be helpful.*
>
> *[Focus group 4, Interviewee 5]*

Theme 4: Encouragement and Motivation Were More Salient Incentives Than Monetary Rewards

Gamification and Rewards: Nonmonetary Rewards

When asked about rewards, most participants expressed that encouragement and nonmonetary rewards were motivating.

> *If you reach a goal, maybe,...you will get in this, a motivating statement, you know, as an incentive or a bunch of balloons goin', confetti exploding, you could maybe get a star.* [Focus group 2, Interviewee 1]
>
> *Maybe even just a motivational somethin', say, some kind of quote...even if it was just, "Good job. You - you did not smoke X number of hours today," or "You smoked less by X percent today." That's the reward right there.* [Focus group 8, Interviewee 3]

A few participants noted that receiving advice or feeling accomplished was rewarding.

> *I just like when [it] lets me know that I've accomplished my goals for today.* [Focus group 7, Interviewee 2]
>
> *I just need somethin' to keep me motivated, like a tip a day.* [Focus group 5, Interviewee 2]

As one participant surmised, the app should be a place, "where you can get encouragement...or you can encourage somebody" [Focus group 2, Interviewee 1].

A few participants expressed that tangible incentives are not as encouraging as the benefits of quitting for one's own health.

> *Yeah, it's not about the money, the incentives. It's what I got to do to live longer.* [Focus group 5, Interviewee 2]
>
> *I have a little girl that I gotta live for, so I'm tryin' to do better with- the smokin'...So that's...motivating me to stop.* [Focus group 6, Interviewee 7]

One participant noted that interacting with others within the app and reaching improvement milestones would be rewarding.

> *I don't really care to be rewarded, because I want to quit smoking. So, I just want the motivation there in the app, tracking...how many cigarettes that I, you know, didn't smoke or whatever, you know, form of tobacco you use. And then just-just having the motivation...* [Focus group 7, Interviewee 8]

Gamification and Rewards: Provision for Diverse Reward Options

Other participants expressed that although money is not the most important motivation, it may be important to some people; hence, allowing participants to choose their incentives was ideal. Some participants mentioned financial rewards, such as gift cards or payments.

> *Some apps give you like daily points if you log in daily. So, if you can get a reward for logging in daily and then it could add up to getting the gift card, getting, you know, PayPal transfers, I think that would be pretty enticing.* [Focus group 7, Interviewee 7]
>
> *It always works better when there's options versus you only have maybe one thing that you can do. So, it might be, oh, a cash app payout or Amazon, but then for the next person they might not really want that, they want something else.* [Focus group 7, Interviewee 4]

Discussion

Principal Findings

As more mHealth apps for tobacco cessation are introduced each year, it is critical that these apps are built to serve everyone, including priority populations. Increasingly, apps tailored for Black adults have been introduced to confront health inequities, with an emphasis on iterative design using formative work from members of the target population [37]. Themes and subthemes from the focus groups revealed a strong preference for certain features, including the type and presentation of content in the app, inclusivity, user experience, tracking capability, professional and social support, gamification, and rewards. Preferred features also aligned with components of the self-determination theory, thereby enhancing the significant role that these features may play in the usage of an mHealth app. These findings provide insight into what app features deter or promote app receptivity, and how to attract Black adults who use tobacco products to use an mHealth app for smoking cessation.

Comparison With Previous Work

In our study, we found that participants desired an app with features that highlight representation and promote inclusivity. To do this, participants recommended that an mHealth app should include testimonials, images, and videos featuring Black adults. Prior studies examining preferred features of mHealth apps for Black women have found that participants desire an app to include a directory of nearby Black female health care providers within their community [38,39]. Having racial concordance with a health care provider can help participants feel they have someone with whom they can relate [39]. One way that representation can be achieved in an mHealth app for tobacco cessation is to have a video testimonial by a Black former tobacco user included in the app, with the person sharing their experience with quitting as well as the health benefits experienced after quitting.

XSL•FO
RenderX

We also found participants desired in-app personalization of content and user experience based on their attributes, such as race, gender, and tobacco use habits and experience. Our findings suggest that to improve the user experience, mHealth apps should allow for personalization based on several factors, not just race. This may lead to a more robust experience for the app user. Further, several participants emphasized how the hypothetical mHealth app should feature a diverse range of people with different perspectives, experiences, and identities. This is consistent with findings in one study on app development where participants desired a diversity of people within an app, specifically wanting "everyone" to be included [40].

Similar to our study, previous research has shown that people are interested in an app with relevant health information and statistics [28]. This finding suggests that when health risks and statistics are personalized, the data are more relatable. Providing personalized content and feedback is associated with increased engagement with mobile app interventions [41]. For example, in an mHealth app for tobacco cessation, including statistics about the rate of cardiovascular disease or cancer for Black tobacco users compared with nontobacco users may increase engagement.

Another important finding in this study is that while participants were in favor of representation within the app, they were understandably hesitant or resistant to an app that focused solely on their racial identity. A previous study on mHealth apps for smoking cessation noted similar concern [28]. This perspective may stem from the justified mistrust of the health community and historical mistreatment of Black people in health care and research [42-44]. In a study that examined mHealth research receptivity among Black men, over a quarter (27%) of men and nearly a third of Black women (30%) identified "mistrust of researchers" as a barrier to participation [45,46].

While a more inclusive but nontargeted app is preferred, outreach strategies to reach the Black community were suggested, including marketing at events for the Black community, marketing by Black influential figures or celebrities on social media, and promotion by Black influencers. This finding suggests that having a known source may engender feelings of trust [47]. Furthermore, in recent years, health campaigns have begun working with influential figures such as pastors or influencers to promote health interventions, including vaccine campaigns [47] and physical activity and healthy eating [48,49]. Influencers can leverage their social influence and reach their audiences directly to promote health interventions [50,51], which could be used to increase app receptivity within the Black community.

In addition, with the high rate of social media use by Black adults [25] and the inclusion of social media as a tool for health promotion and intervention dissemination due to wider reach, scalability, and cost-effectiveness [52], targeted social media campaigns can be beneficial. In tobacco cessation studies, the use of social media platforms for recruitment has shown success, especially for minority populations that are typically hard to reach [49]. In one study by Bricker et al [52], tailoring of a social media campaign to disseminate an mHealth app in a way that focused on self-control and health values was found to be cost-effective and associated with high reach based on the number of clicks and conversion to app installation. The use of social media platforms to disseminate an mHealth app for tobacco cessation targeted for Black adults can increase the likelihood of awareness of the mHealth app, which may convert into more interest and greater use.

Furthermore, prior research to investigate smokers' reactions on social media platforms revealed that comments and the type of reaction such as "love" or "haha" were a reflection of the level of motivation with regard to readiness to quit [53]. This suggests that although social media can be used to enhance the visibility of mHealth apps for tobacco cessation, it can also stimulate motivational processes by serving as a space for cessation-related posts that contain culturally representative narratives, prompting users to share their own motivations and goals for quitting or positively respond to comments that are reflective of their own experiences. This way, social media is not only a tool to promote the mHealth app but can also help to assess qualitative measures such as levels of engagement and motivation to quit.

Our findings also revealed the importance of an in-app community that offers accountability through supportive connections (eg, through health care providers and quit buddy programs). Previous research on mHealth apps has found that many people desire the ability to connect with health care providers within apps [39]. One study examining supportive accountability through counselor monitoring and supportive advice found that having a trusted expert within an mHealth app intervention for smoking cessation led to increased app engagement [54]. In another intervention that used peer-to-peer exchanges between participants seeking smoking cessation resources and communications from experts with treatment-related questions for participants to discuss, doubled sustained abstinence was observed compared to those who only used nicotine patches and had access to a cessation website [55]. Further, the effectiveness of mHealth interventions can be enhanced by human and social support [56,57].

Although open to connections, participants were hesitant and less receptive to having family or social media integrated within the app due to privacy concerns. Other studies examining receptivity to social media on mHealth apps have similarly found that most participants did not want social media integration, citing privacy concerns [39]. Although privacy is a major concern, social media play a significant role by serving as a platform through which health-related behavior change interventions can be delivered and health-related connections or support groups developed in a meaningful way [58,59]. For Black adults who use tobacco products, addressing the privacy concern in a transparent way may improve receptivity to the integration of elements of social media into the intervention.

In contrast, some people prefer having emotional support, such as encouragement, from friends and family [60,61]. Studies have found that stigma against individuals who smoke can prevent them from seeking care [62]. One study found that negative comments from one's social network about their smoking habits can even lead to a decrease in quitting progress

XSL•FO
RenderX

[61]. To combat this concern, any external connections to the app should be optional.

App tracking capability was also an important feature for accountability and has been identified as a desirable feature and method to promote accountability in other studies [39,54]. Several mHealth interventions use the tracking feature to help monitor chronic health conditions and medication intake [63,64]. One qualitative study that explored experiences of Black adults who use tobacco products with a specific mHealth app for smoking cessation identified that the tracking feature was highly preferred [28]. With mHealth apps for tobacco cessation, tracking of the rate of use of tobacco products, cravings, or money saved over a period of time from less use can lead to sustained motivation and cessation-related behavior.

Lastly, we found that while some participants said that financial incentives could attract some people to use the app, many participants did not think financial incentives were necessary to attract users to the app. Prior research suggests that financial incentives can modify or increase adherence to desired behavior changes, like exercise [65], dietary changes [66], or engagement with a state Quitline [67]. However, the sustained provision of financial incentives may not be feasible for mHealth apps long term, nor are they always necessary. In one study examining motivations and barriers to participating in mHealth research among Black males, approximately 40% indicated that offering financial incentives would motivate participation, while only 16% indicated that a lack of financial incentives was a barrier to participation [45]. Similar rates were also seen among Black women, 39% and 15%, respectively [46]. Continued engagement with an app is further augmented by other considerations, like the content shared [68]. Therefore, while financial incentives are desirable, their absence may not significantly deter participation with mHealth interventions. This finding aligns with existing research that the gamification (eg, inclusion of game elements and rewards) of mobile apps can reward and motivate app users [69,70] and promote behavior change [71].

Design Implications for App Development

To enhance the translation and application of our findings to an mHealth app development, we mapped out each subtheme and domain feature into examples of concrete mHealth app features with pertinent processes from the self-determination theory. We also included examples of ethical and privacy considerations, as well as potential metrics to consider during implementation. The map, as outlined in Table 3, shows how representation and inclusivity, personalization, content, accountability, tracking and user experience, social and professional support, and nonmonetary incentives can be operationalized into actual, concrete features within an mHealth app for tobacco cessation.

XSL•FO
RenderX

Table . Design implications for mobile health app with preferred features.

Subthemes and domains of app features	Examples of concrete app features	Self-determination theory components	Privacy/ethical considerations	Potential metrics
Representation and inclusivity	• Video testimonials from other Black tobacco users • Culturally relevant language	• Relatedness • Autonomy	• Avoidance of identifying information of individuals in videos or photos • Opt-in for culturally relevant material, instead of it being the default • Informed consent • Avoidance of racial profiling in content	• Amount of time spent and frequency of viewing culturally relevant information • Rate and frequency of opt-in for culturally relevant material
Personalization	• In-app customization of goals, quit date, reminders, and prompts • Personalized diary	• Autonomy	• User-controlled input of information • Password-protected storage and opt-out option	• Achievement of personal goals • Number and frequency of diary entries
Content	• Health risk statistics relevant to the target user	• Relatedness • Competence	• Ensure credibility of the source of information • Avoidance of the use of sensitive language or medical jargon	• Completion of content sections
Accountability	• Quit buddy, daily check-in	• Autonomy • Relatedness	• User opt-in • Anonymization of profile	• Daily active use
Tracking and user experience	• Tracking tools for mood, cravings, number of cigarettes used, and days without use	• Autonomy • Competence	• User control on the type of information to track or delete • Secure or password-protected storage of tracked data	• Daily active use
Social support	• Anonymous in-app community	• Relatedness	• Anonymization of user profile • User opt-in for participation or for integration with social media	• Number of users who opt-in • Number and frequency of comments and posts on the community board
Professional support	• Quitline or access to a tobacco treatment specialist, trusted expert chat	• Competence	• Informed consent to interact with a professional • Encryption of messages	• Number and frequency of use or messages sent to an expert • Number of times the Quitline button or icon is used
Nonmonetary incentives	• Badges, points	• Competence	• Option for private mode where reward is only seen by the user • No shaming or negative language during relapse	• Rate of badges or points earned

Limitations

A limitation in this study is that findings may not be generalizable. First, we used a convenience sample online and recruited from one social media platform. This may have limited the sample size as well as the diversity of participants in terms of gender, age, educational level, and income. Conducting the focus groups online, as well as the requirement of a history of app usage or willingness to use an mHealth app in the future for participation in this study, further limits the diversity of

XSL•FO
RenderX

perspectives about features of mHealth apps for tobacco cessation. Furthermore, findings may also not be generalizable to Black adults outside of the United States due to cultural differences and other factors that may exist across countries. Obtaining the perception of Black adult tobacco users who are not receptive to the idea of mHealth apps for tobacco cessation may provide additional insight into how best to develop and market these apps in a more inclusive way.

Conclusions

Our findings confirm the need to design mHealth apps for tobacco cessation with features that are reflective of cultural relevance, inclusivity, and diversity of experiences without excessive targeting and support motivation as stated in the self-determination theory [19-21]. Consistent with Perski and colleagues [72], engagement with mHealth apps increases when design features support personal relevance, motivation to quit, and credibility. Our findings provide insight into the improvement of existing apps and future development of an mHealth app that can appeal to Black adults who use tobacco products, potentially increasing app use, engagement, and successful cessation. Findings from this research can also serve as a groundwork for future research to explore the effectiveness of an mHealth app culturally tailored with preferred features optimized to enhance engagement by Black adults who use tobacco products and to identify other factors that may improve usage and lead to better outcomes for the target population.

Abstract

Background: Mobile health (mHealth) apps have shown promise to support recovery from substance use disorders. However, evidence on engagement and efficacy is still inconclusive.

Objective: This study aims to identify design considerations for optimizing engagement in mHealth apps for those recovering from problematic substance use, by analyzing real-world experiences with co-designed app features.

Methods: We co-designed, deployed, and evaluated an mHealth app. Initial co-design interviews with 14 individuals in recovery led to 3 new features integrated into an existing mHealth app. The app was deployed for a 6-week trial with 53 participants using it during their daily routines without researcher supervision. Usage patterns were analyzed throughout the trial period, and follow-up interviews with 12 app users foregrounded subjective usage experiences and considerations for future design.

Results: We developed 3 new features following co-design interviews: a goal-setting feature, a craving tracker, and a meetings log. Usage metrics revealed mixed engagement, with 45.3% (24/53) of users actively engaging with the app throughout the trial. These active users opened the app 27.1 unique times on average, with a retention rate after 30 days among active users of 45.8% (11/24), exceeding the typical mobile app retention benchmark of 7% after 30 days. Interviews revealed that participants preferred app functionality to extend beyond substance use domains to support other dimensions of their lives not directly pertaining to substance use, such as general goals and daily routines. Participants further suggested that recovery apps should act as private digital journals while also providing a sense of community and connection to broader recovery ecosystems. Additionally, mHealth designs that allow users to configure their own personalized recovery pathways in the app can benefit some users who appreciate increased autonomy, while others may become overwhelmed by a lack of prescriptive guidance.

Conclusions: It is valuable to incorporate iterative co-design methodologies into digital health and recovery app research to help optimize engagement. Furthermore, recovery apps can benefit from flexible designs with customizable degrees of user autonomy. Future designers can better cater to individual user preferences by personalizing mHealth designs so that they strike a balance between system control and user control over digital recovery pathways.

Introduction

Mobile health (mHealth) apps have become popular tools to manage personal health, offering inexpensive and accessible health guidance, self-monitoring of progress, and interactive communication with clinicians, among other capabilities [1]. A major aspect of some individuals' personal health is use of substances, and recovery from disordered substance use. "Recovery" is defined by the individual and can have a variety of meanings, from reducing problematic use to practicing full abstinence [2,3]. Specialized mobile health apps have become popular tools to facilitate all forms of recovery, with many commercially available in iOS and Android app stores [4-6].

Prior research finds some potential for mHealth apps to facilitate recovery [7-10]. However, the effectiveness and engagement of these interventions remain unclear [8,9,11-13]. Effects are often minimal, or only notable when the app is used in conjunction with other non-app-based treatments [14-16]. Furthermore, many studies in this field use a randomized controlled trial methodology. These studies often compare any usage of the app to treatment-as-usual, and tend to overlook the details of how users engaged with particular app features and their motivations behind specific engagement patterns [8,12,17-19]. Therefore, some researchers argue that studies "should not assess the success of addiction recovery apps based only on objective measures of changes in substance use" [12], and should instead aim to understand users' subjective experiences when using such tools as a way to evaluate quality.

This body of research may additionally benefit from a greater focus on the designer's point-of-view, unpacking the details of how digital recovery tools can be designed to best support their users [17,18], rather than only studying user outcomes after the app has already been built and deployed. Careful user-experience design and research play key roles in the success of mHealth apps [12,19], as they can involve human-centered techniques such as value-sensitive design [20,21] and participatory or collaborative design (co-design) [22-24]. In the field of mobile recovery apps, however, such human-centered design techniques are scarce [13]. This study incorporates the co-design and deployment of an mHealth recovery app to investigate the real-world experiences of people dealing with problematic substance use. In doing so, we shed light on practical design considerations to optimize app engagement among this population.

There is a small but growing body of research that shares the aim of centering end users' perspectives to design engaging mHealth recovery apps [25-28]. One prior study is particularly relevant: Jones et al [29] investigated how individuals engaged with an early version of a self-tracking app, identifying considerations for future designs. Similar to our work, Jones et al deployed a working prototype of the tool to stimulate discussion with participants and gather mixed methods usage data. Notably, Jones et al [29] focused only on features that support day-to-day activity tracking, discussing themes pertaining to the types of activities participants tend to track and how they preferred to track them. Herein, we used similar methodologies in pursuit of similar aims, but importantly expanded beyond activity tracking to also investigate the design of goal-setting features and several other mHealth feature types.

Specifically, our research objective was to gain a feature-level understanding of how to create an mHealth app that engages people on their recovery journey. We achieved this objective by co-designing new app features and examining how individuals in recovery perceived and interacted with them during their day-to-day lives over a 6-week period. We took a mixed methods approach to evaluate both quantitative usage metrics and qualitative accounts of users' experiences with the new features.

Methods

Overview

We adopted a research through design (RtD) approach [30-32]. RtD involves conducting research that "employs the methods, practices, and processes of design practice, with the intention of generating new knowledge" [31]. RtD encompasses the hands-on practice of designing a new tool, evaluating its functionality, and reflecting on its design to identify implications for future technologies. In accordance with this hands-on approach, we collaborated with the developers of an existing mHealth app, Zamplo [33], to complete three phases of this work: (1) initial co-design interviews; (2) design, deployment, and a 6-week app trial; and (3) user-experience interviews.

The Zamplo mHealth App

Zamplo's existing functionality does not cater specifically to substance use recovery, as it is used as a general mHealth tool. Users of mHealth technologies tend to face difficulties using a suite of different apps with several overlapping and fragmented features, often preferring a single, flexible unified platform instead [34]. Zamplo aims to overcome these issues with an array of flexible digital health capabilities within one platform to support multiple aspects of personal health. Existing Zamplo capabilities include customizable reminders, daily personal tracking, and visualizations of medications and activities, as well as tracking of mental and physical health symptoms, and management of health documents, to-do lists, notes, and important contacts.

For this study, we configured these features to not assume the preferences of users, such as what specific health metrics they may want to track, what types of goals they will set, or how frequently they prefer to receive reminders. Instead, we configured Zamplo as an open-ended platform, allowing users to self-track, set goals, create reminders, and access several other mHealth features, in whichever ways they choose, without enforcing any planned usage patterns. This open-ended approach allowed for naturalistic observations of how individuals organically use mHealth features when not pushed to engage in a particular way.

We co-designed new features to add to the Zamplo platform and used Zamplo as a technology probe. Hutchinson et al [35] define technology probes as technological artifacts that guide researchers in understanding their users in a real world setting and inspire participants to think creatively about new potential designs [35]. Hence, Zamplo was used as a concrete artifact to

XSL•FO
RenderX

ground participants' interviews, stimulate discussions of users' experiences, and crystalize users' needs. It was a particularly well-suited technology probe as it was created and approved for the secure storage of health data, allowing extensive possible usages in the trial than available in most mHealth apps. This research consisted of three phases, as outlined below.

Phase 1: Initial Co-Design Interviews

Participants

This research began with an initial round of interviews to capture design ideas from individuals with experience recovering from substance use disorders. Participants were recruited from 5 local addiction treatment centers. Of the 23 individuals who signed up to participate, 14 attended an interview. Informed consent was obtained via an electronic consent form and CAD $20 (USD $14.76) electronic gift cards were offered to all interviewees.

Procedure

The research team collaboratively developed a semistructured interview protocol, and 45-60 minute interviews were conducted virtually by one interviewer. Participants were first asked about their recovery history and experiences using technology. This contextualized the primary component of each interview, which was a demonstration of the existing Zamplo platform, followed by inquiry into participants' impressions and ideas for future designs.

Interviews revealed participants' stated needs regarding mHealth technologies and their perceived role in recovery. While the interview protocol provided a framework for discussion topics, the direction of each interview was guided by participants [36]. As such, participants were encouraged to speak openly and creatively about their ideas for Zamplo and were prompted to provide both positive and negative feedback. To mitigate social desirability bias, the interviewer clearly stated that the app was not their own and that all critiques are welcome.

Data Analysis

Interviews were recorded using Zoom (Zoom Video Communications, Inc) and transcribed using Rev AI (Rev.com, Inc) transcription software. The interviewer then manually reviewed and corrected each transcript, before manually analyzing transcripts using the NVivo (Lumivero) platform. A generative open-coding approach was taken for each transcript, iteratively generating, refining, and categorizing original codes throughout analysis [37]. The goal of coding was to identify actionable design implications for new Zamplo features. Several design themes based on the interviews were identified and collaboratively refined via discussions with the research team. These results were relayed back to Zamplo developers to implement, launching the next phase of the research.

Phase 2: Design, Deployment, and 6-Week App Trial

Overview

Interview themes from Phase 1 laid the foundation for creative co-design discussions with the research team and the lead Zamplo developer. Discussions resulted in several low-fidelity wireframe-style prototypes [38] of potential new features, based directly on input received from participants. A new trial version of Zamplo was then deployed on iOS and Android app stores, and recruitment opened. There were two goals for this trial: first, to gather quantitative usage metrics to evaluate usage patterns and engagement; second, to provide participants with a concrete mHealth app experience to stimulate productive reflections during Phase 3 interviews. The following sections detail the methods of this trial.

Participants

Participants were recruited through posters in several treatment centers and online advertisements. Screening excluded those who were not in Canada or were not currently attempting to stop or reduce their substance use. Informed consent was obtained via an electronic consent form, after which they were provided a direct link to download Zamplo and begin their 6-week trial.

Procedure

This was a single-arm trial in which all participants were given the same mHealth intervention. Recruitment occurred from November 29, 2024, to January 17, 2025. After creating a Zamplo account, participants navigated through a text-based tutorial of the features available to them. The tutorial encouraged participants to explore all features and use the app in ways that felt most natural to them. They were further informed that they were not required to use the app to receive their monetary incentive, and all data they entered into the app will be kept entirely private. Participants were provided with an email address for further technical help, if needed. Overall, participants were left to independently engage with the app during their regular lives.

When participants reached the end of their 6-week trial, the app directed them to a final survey to provide information about their demographics and substance use history, rate the helpfulness of the app, and provide consent to be contacted for a follow up interview. They were then offered a CAD $20 (USD $14.76) electronic gift card for their participation. Those who did not submit a final survey after their trial period were considered to have dropped out of the study and were not included in the final analysis.

Data Analysis

Data were collected on the number of times participants opened the app, the duration of each app usage session, and the frequency with which participants used each individual feature. These data informed descriptive statistical analyses of engagement. Furthermore, participants were divided into categories based on demographics (gender, age, and ethnicity), recovery goals (abstinence or harm reduction), most problematic substance (alcohol, cannabis, or other illicit substances), and perceptions of Zamplo's helpfulness. Engagement was compared across groups.

Phase 3: User Experience Interviews

Overview

To gather further insight, we conducted follow-up interviews with a subset of Phase 2 app users, inquiring about their experiences with the app and suggestions for future designs. These qualitative interviews added nuance to quantitative app

XSL•FO
RenderX

usage metrics. While Phase 2 usage metrics provided valuable information on how frequently each feature was used, interviews shed light on *why* participants chose to use or not use particular app features, and other subjective experiences with the platform.

Participants

After participants completed their 6-week app trial, 42 consented to be recontacted for a follow-up interview. Researchers contacted 22 of these participants to schedule interviews. Others were not contacted due to suspected fraudulent participation, zero app usage during Phase 2, or not engaging meaningfully with the final survey, such as by skipping all questions. Of these 22 participants, 12 attended an interview. Informed consent was obtained via an electronic consent form, and CAD $20 (USD $14.76) electronic gift card incentives were offered to all interviewees.

Procedure

Interviews were 45-60 minutes in duration and conducted virtually by the same interviewer as in Phase 1. Interviews consisted of 3 main types of questions: the participant's history using apps in general during their recovery, their experiences with Zamplo during the app trial, and questions prompting the participant to brainstorm about "ideal" mHealth app functionalities to support their recovery. Both positive and negative feedback were encouraged.

Data Analysis

Interviews were recorded using Zoom, and transcribed using Rev AI transcription software. Each transcript was manually reviewed and corrected by the interviewer.

Transcripts were manually analyzed using the NVivo (Lumivero) platform, and coding was completed in 3 stages. The purpose of the first stage was to generate a codebook [39]. To do so, the interviewer conducted a preliminary round of coding. Coding was inductive [36], and after becoming familiar with transcript data and noting initial impressions, the coder generated original codes using an open-coding process [37]. Several low-level preliminary codes were created and clustered into a hierarchical structure. High-level categories were then refined to create a codebook based on collaborative discussions among the research team. A copy of the final codebook is available in Multimedia Appendix 1.

The initial coder and a second coder then used the codebook to code the full set of transcripts, making up the second stage of analysis. Both coders coded the same first transcript, then met to discuss coding disagreements and refined the codebook based on consensus. They repeated this process with a second transcript. After all remaining discrepancies in their interpretation of the codebook were resolved, each coder was randomly assigned 5 of the remaining transcripts to independently code using the codebook. Coding focused on capturing meaning as communicated by the participants (semantic coding), rather than attempting to identify implicit meaning behind participants' words (latent coding) [36,37].

Once all transcripts were coded using the codebook, the interviewer conducted a final thematic analysis of the coded transcripts, comprising the third stage of analysis. This final, high-level analysis generated meaningful themes with accompanying illustrative quotes to characterize how participants experienced Zamplo, and their values regarding mHealth apps for recovery.

Ethical Considerations

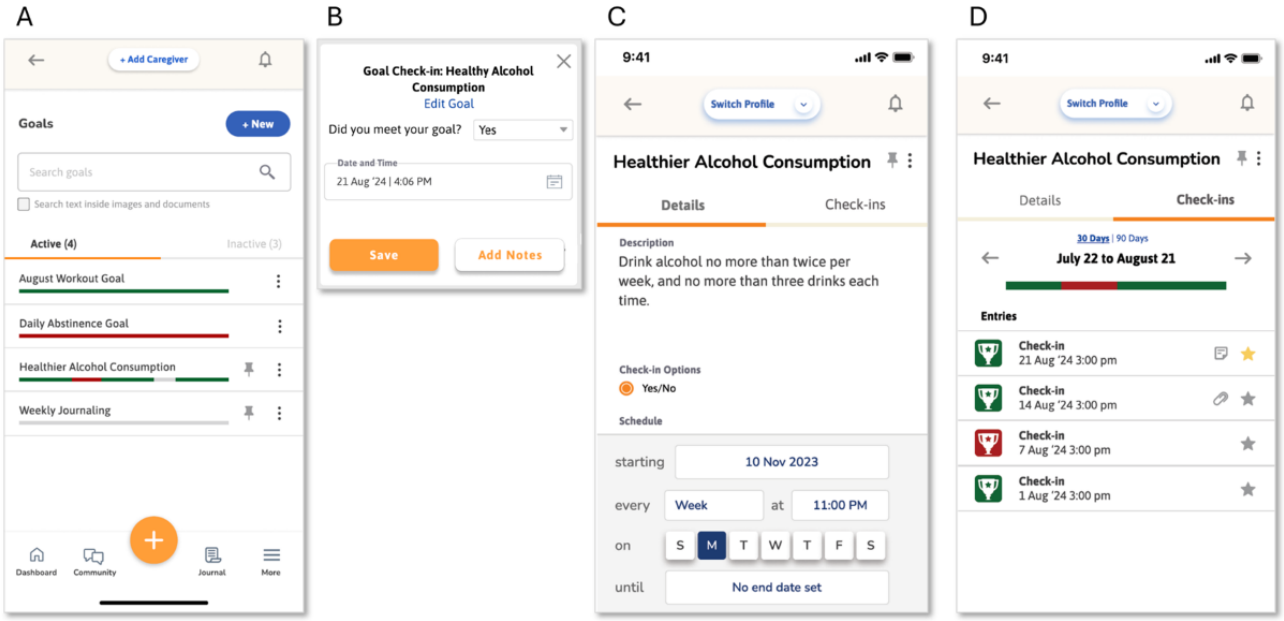
All phases of this work were approved by the University of Calgary Conjoint Faculties Research Ethics Board (REB24-0015). Informed consent was obtained via electronic consent forms for each phase. CAD $20 (USD $14.76) electronic gift cards were offered to all interviewees; participants were not required to meet any app engagement thresholds to receive the incentive. Participants were informed that Zamplo usage data were completely anonymous and confidential, and that survey data would be kept confidential with identifying information stored separately from deidentified survey data using anonymous participant identifiers.

Results

Phase 1: Co-Design Results

Overview

A total of 14 individuals participated in the initial co-design interviews. The mean interview duration was 58.9 minutes, with the longest interview lasting 107 minutes and the shortest lasting 47 minutes (13.7 hours in total). Themes from the initial interviews described several design implications for new Zamplo features. After iterative co-design discussions, 3 features were deemed feasible and worthwhile: a goal-setting feature, a craving tracker, and a meetings log. Features that were not included due to technical or resource constraints were a sobriety tracker and a mood tracker. Sobriety can instead be tracked within the goal-setting feature, and aspects of mental health can be tracked with existing Zamplo features upon user customization. The following sections detail the design and rationale of each new feature.



New Feature 1: Goal-Setting

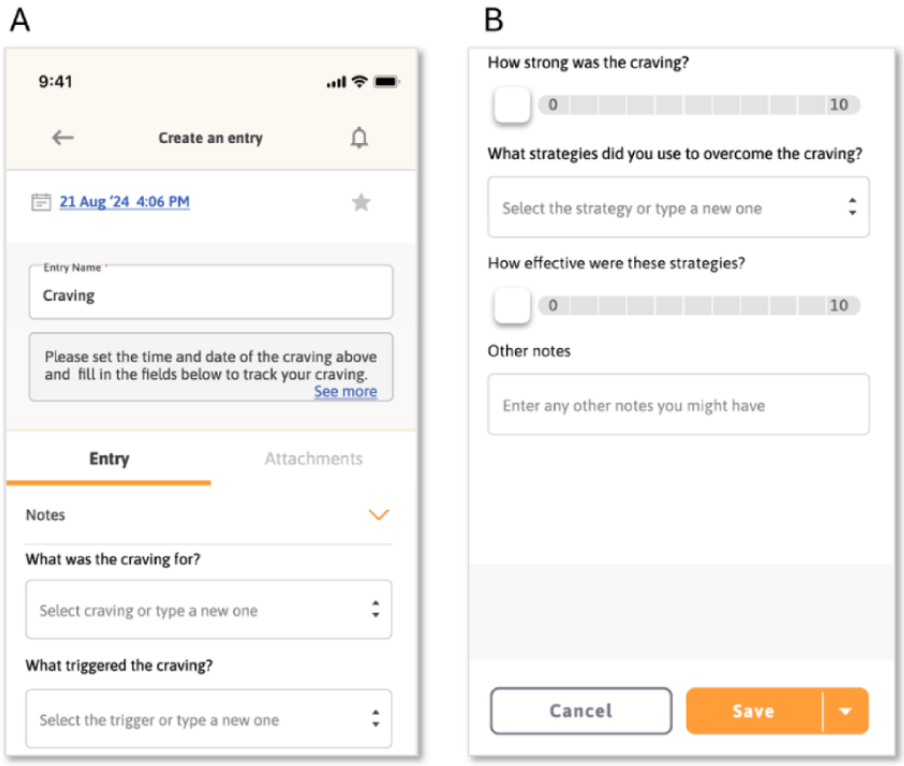
During co-design interviews, participants emphasized that seeing ongoing progress of their recovery is crucial for their motivation. A visual anchor can keep them focused on and accountable to their recovery goals. However, they also described feeling frustrated and demoralized by existing sobriety tracker apps that reset and erase all previous data upon a relapse. This gave rise to the design idea of a nonconsecutive goal tracker that does not add more feelings of shame to relapses and allows imperfect adherence to goals. In contrast to sobriety trackers that only track consecutive sober days, this feature acknowledges missed days without resetting the tracker. Users can create any new goal to track, modify a goal at any time, create a flexible goal end date, and customize time intervals for regular "check-in" notifications (daily, weekly, or otherwise). At the user-specified check-in intervals for each goal, the feature generates a goal check-in notification, where users select "Yes," "No," or "Somewhat" in response to the question "Did you meet your goal?" A visual progress bar is gradually created over a 30- or 90-day timeframe for each goal, reflecting the history of the user's goal progress according to their check-ins. The progress bar displays both successful and unsuccessful days. Figure 1

XSL•FO
RenderX

shows final mock-ups of this feature. Importantly, this feature can be used to set and track goals outside of substance-use as well.

Figure 1. Goals feature mock-ups. (A) All active goals displayed with current check-in progress. Red bars indicate negative check-ins; green bars indicate positive check-ins. (B) An example of a scheduled goal check-in notification for one goal, asking if the user met their goal, with a selected option ("Yes") and a date and time. (C) Viewing or editing one particular goal, including the title, description, and customized check-in schedule. (D) Detailed history of goal check-ins for one particular goal.

New Feature 2: Craving Tracker



Interview analysis also revealed a desire to track cravings, along with triggers and solutions for each craving and additional health data. Participants explained that they would benefit from tracking cravings alongside several other metrics to understand potential reasons for the craving. For example, P008 described what they would like to see in a future iteration of Zamplo:

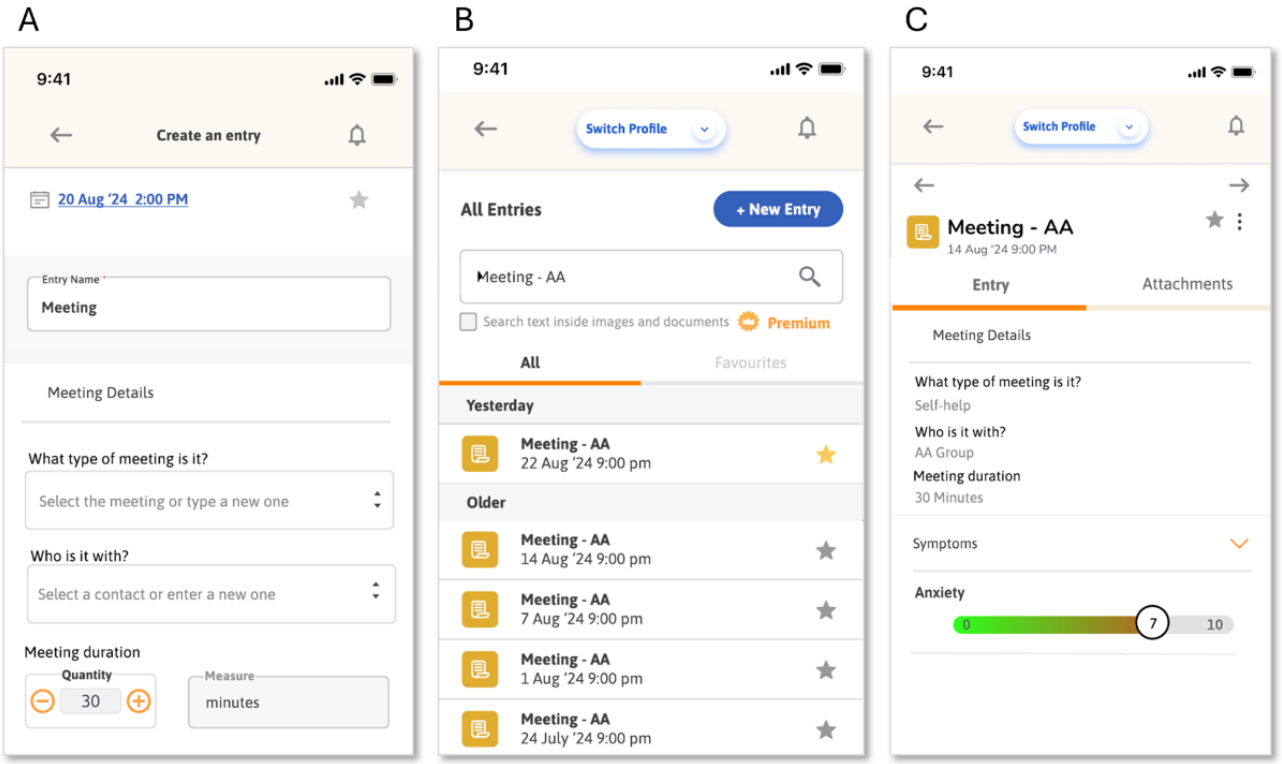
> *It'd be kind of cool to track when you're getting cravings, and then you can determine why you got that craving. Maybe because your physical activity was down, maybe because you stopped going to meetings, or maybe you're doing too many meetings, or too much physical activity or too much work. So, it'd be cool to track your balance that way so you can figure out where you go wrong.* [P008]

These types of participant sentiments led to the design of the craving tracker feature (Figure 2), which allows users to log details of each craving. The craving tracker is shown prominently on the main app dashboard for users to tap any time they experience a craving.

XSL•FO
RenderX

Figure 2. Craving tracker mock-ups. (A) The top of a new craving entry page. (B) The bottom of the entry page (scrolled down).

New Feature 3: Meetings Log



The final feature that arose from initial interviews was a meeting log. Participants described the importance of keeping track of meetings, appointments, and other treatment sessions. Participants not only needed reminders for meetings, which they can create using Zamplo's existing activity tracker, but they also wanted to log the details of each meeting to revisit in the future. P004 describes how tracking Alcoholics Anonymous meetings can boost their motivation:

> *If you documented your meetings list, you would see, 'wow, I went to a hundred meetings in the last 90 days,' or something like that. It shows how much time and effort you put in.* [P004]

Figure 3 depicts final mock-ups of the meetings log feature.

Phase 2: App Usage Patterns During the 6-Week Trial

Figure 4 contains a CONSORT (Consolidated Standards of Reporting Trials) flow diagram of participation throughout this single-arm trial. Due to widespread online recruitment channels, fraudulent participation posed issues for this second research phase. Therefore, we established several authenticity screenings that effectively screened out fraudulent participation.

Figure 4. CONSORT (Consolidated Standards of Reporting Trials) diagram for Phase 2.

Of the 203 accounts initially created, 21 were suspected fraudulent due to circumventing the mandatory screening questionnaire meant to be completed before account creation. A further 32 participants were suspected fraudulent after completing their final survey after the trial, due to mismatched demographic responses when compared to initial screening, such as their age decreasing. The Zamplo usage data pull included 118 accounts. However, several accounts shared the same device address, indicating a possibility that each account did not represent a unique person. Accounts were designated

XSL•FO
RenderX

authentic if they did not share an address with other accounts. As shown in Figure 4, a total of 65 potentially fraudulent accounts were detected using this approach. The final sample size of authentic participants was 53.

App users were divided into several subcategories based on demographics, recovery approach, most problematic substance, and ratings of the app's helpfulness. These groups provide important context for design, as they demonstrate which sectors of the community found the app most useful. The final numbers of authentic users in each group are shown in Table 1.

Table 1. App user groups, with numbers of authentic and active users.

Group	Authentic users, n/N (%)	Active users[a], n/N (%)
All users	53/53 (100)	24/53 (45.3)
Gender		
Women	29/53 (54.7)	15/29 (51.7)
Men	23/53 (43.4)	8/23 (34.8)
Recovery goal		
Abstinence recovery goals	36/53 (67.9)	14/36 (38.9)
Harm reduction recovery goals	17/53 (32.1)	10/17 (58.8)
Perceived app helpfulness		
Somewhat to very helpful	35/53 (66)	13/35 (37.1)
Somewhat to very unhelpful	12/53 (22.6)	9/12 (75)
Most problematic substance		
Alcohol is most problematic substance	18/53 (34)	9/18 (50)
Cannabis is most problematic substance	14/53 (26.4)	5/14 (35.7)
Other most problematic substance	21/53 (39.6)	10/21 (47.6)
Age group (years)		
18-29	14/53 (26.4)	5/14 (35.7)
30-39	21/53 (39.6)	14/21 (66.7)
40-59	11/53 (20.8)	4/11 (36.4)
Race and ethnicity		
White	32/53 (60.4)	14/32 (43.8)
BIPOC[b]	18/53 (34.0)	7/18 (38.9)

[a]A user was considered "active" if they opened the app on 2 or more separate days, excluding the first and last days of the study period.

[b]Black, Indigenous, and People of Color.

The designation of an *active* user was created to ensure that usage data were analyzed from those who meaningfully interacted with the app. An active user was defined as someone who used the app during at least 2 separate 24-hour intervals. Usage in the first and last 24-hour periods of a person's trial did not count toward the active user designation, since those intervals included activity required for minimal study compliance. Specifically, the first 24 hours involved downloading the app to begin the trial, and the last involved following a link to conclude the trial. The number of active users in each demographic group are shown in Table 1.

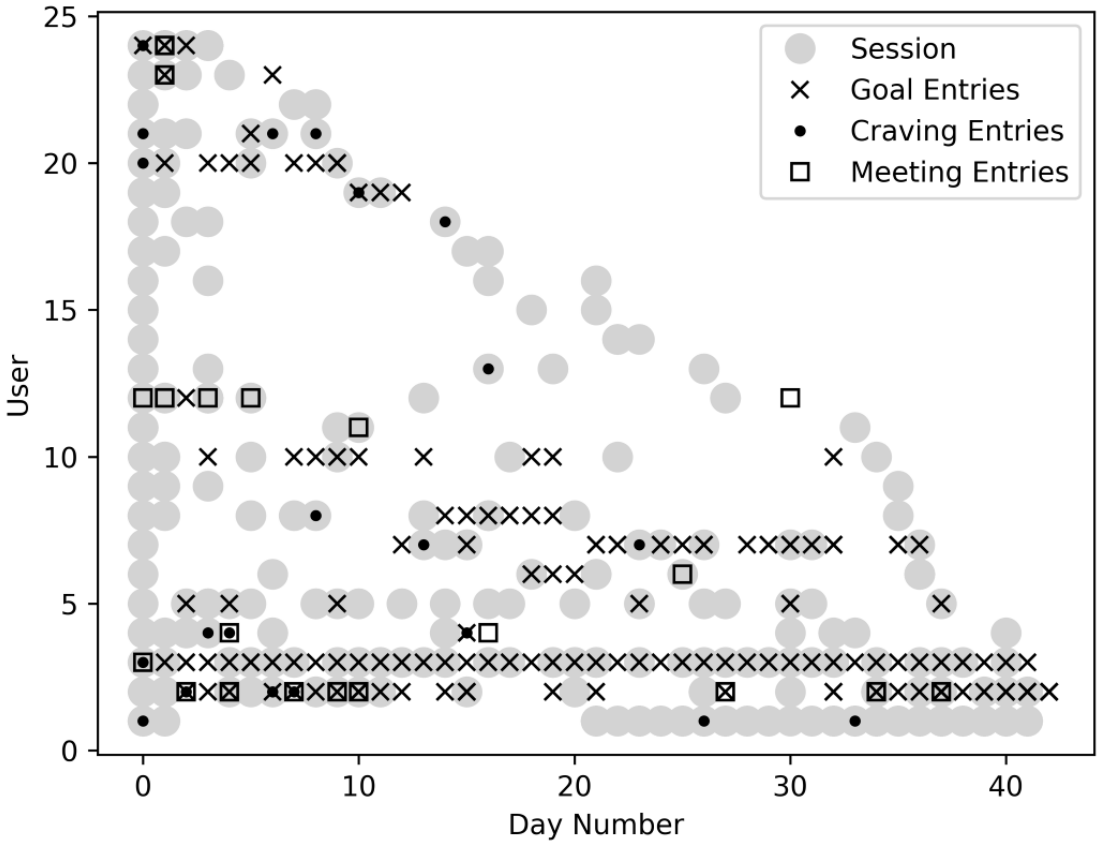
While many of the group sizes in Table 1 are small, they allow for preliminary comparisons between groups. A greater proportion of women actively used the app (15/29, 51.7%) compared to men (8/23, 34.8%). Overall, the greatest number of active users were women (n=15), followed by those aged 30-39 years (n=14), those who identified as White (n=14), and those who aimed to fully abstain from substance use (n=14). However, a higher proportion of users taking a harm reduction approach to their recovery actively engaged with the app (10/17, 58.8%) compared to those taking an abstinence-based approach (14/36, 38.9%).

Table 2 depicts how often the active users in each participant group opened the app over the 42-day trial period. A "session" was logged by Zamplo each time a user opens the app for any reason, either to enter data or simply to view information or explore the interface. Table 2 includes the mean (SD), median (IQR), and top 25th percentile number of sessions for each group.

XSL•FO
RenderX

Table 2. Number of sessions among active users.

Group	Active users, n (%)	Number of sessions over 6-week app trial		
		Mean (SD)	Median (IQR)	Top 25th percentile
All users	24 (100)	27.1 (47.5)	10 (7-18)	18
Gender				
Women	15 (62.5)	37 (57.7)	10 (6-47)	47
Men	8 (33.3)	10.8 (4.5)	11 (7-16)	16
Recovery goal				
Abstinence recovery goals	14 (58.3)	13.5 (10.7)	10 (6-16)	16
Harm reduction recovery goals	10 (41.7)	46.2 (68.0)	14 (7-54)	54
Perceived app helpfulness				
Somewhat to very helpful	13 (54.2)	32.2 (57.4)	10 (6-18)	18
Somewhat to very unhelpful	9 (37.5)	24.2 (33.3)	15 (7-18)	18
Most problematic substance				
Alcohol is most problematic substance	9 (37.5)	34 (67.4)	9 (6-14)	14
Cannabis is most problematic substance	5 (20.8)	11 (3.7)	10 (9-11)	11
Other most problematic substance	10 (41.7)	29 (33.7)	16 (6-47)	47
Age group (years)				
18-29	5 (20.8)	9.8 (2.9)	10 (9-11)	11
30-39	14 (58.3)	38.1 (59.6)	10 (7-47)	47
40-59	4 (16.7)	12.5 (7.7)	15 (6-24)	24
Race and ethnicity				
White	14 (58.3)	36.4 (59.3)	15 (6-24)	24
BIPOC[a]	7 (29.2)	16.1 (16.0)	9 (6-18)	18



[a]Black, Indigenous, and People of Color.

While much variation can be seen in the mean and 25th percentile values, the median number of sessions is relatively stable for most groups. This suggests that a small portion of users had a particularly large number of sessions that inflated the mean and percentile values.

Figure 5 shows the temporal pattern of engagement with the app in general (sessions), as well as engagement with each of the 3 new features over the 42-day app trial. The x-axis represents the day number relative to each person's first day in the trial, and the y-axis represents user indices. Note that the user indices in Figure 5 are randomly assigned to the data in Figure 5 only and do not correspond to the participant IDs used when reporting interview data.

XSL•FO
RenderX

Figure 5. Each day in the trial when active users opened the app (sessions) and made new entries into each of the new co-designed features.

To better observe trends, users are ordered in Figure 5 according to the last day they used the app. When creating a goal, craving, or meeting entry, the user had the option to manually adjust the date that the goal was met, cravings were experienced, or the meeting occurred. Therefore, the goal, craving, and meeting data points shown in Figure 5 are based on the dates manually entered by the user, rather than the dates that the user opened the app to enter the data. Furthermore, sessions (gray circles) reflect the exact dates that each user opened the app. During each session, users may have engaged with the myriad of preexisting Zamplo features, such as activity tracking, medication tracking, creating and viewing charts of personal data, and so on.

Figure 5 depicts the relative popularity of the Zamplo features co-designed during this study compared to users' engagement with the rest of the Zamplo app. For example, users 15, 16, and 17 logged sessions of app usage but did not use the goals, cravings, or meeting features. In contrast, user 3 made nearly daily use of the app and the goal feature specifically. When viewing the full figure, it is clear that most users chose to interact with the newly designed goals, cravings, and meetings features. However, their use of these features varied widely, with some patterns of almost daily use and other patterns of intermittent and infrequent use.

The new goals feature was the most popular. More granular analysis of usage data revealed that, of the 24 active users, 17 created a single goal to track, 3 created multiple goals, and 4 did not create a goal. When users entered data into the app via the new co-designed features, 58.3% (14/24) made at least 1 goal entry, 50% (12/24) made at least 1 craving entry, and 33.3% (8/24) made at least 1 meeting entry.

A common metric for understanding app engagement is the 30-day retention rate, defined as the percentage of users still using the app 30 days after installing it. If all authentic users are included in this metric, 20.8% (11/53) of authentic users were retained after 30 days. This metric can also be calculated using only the active participants who made some effort to use the app, since the others may never have intended to use the app beyond minimal research compliance. In this case, 45.8% (11/24) of active participants were retained after 30 days.

Phase 3: User Experience Interview Findings

Overview

Qualitative interviews contextualized the above quantitative findings by revealing details of how participants experienced Zamplo. A total of 12 individuals from the app trial attended a one-on-one interview with a researcher. The mean duration of interviews was 47.6 minutes, ranging from 38 to 59 minutes (9.5 total hours). Interview participants had a mean age of 32.9 (SD 7.38) years. Participant demographics are shown in Table 3.

XSL•FO
RenderX

Table 3. Characteristics of interview participants.

Measure	Value, n (%)
Demographics	
Gender	
Women	7 (58.3)
Men	5 (41.7)
Age group (years)	
18-29	4 (33.3)
30-39	6 (50)

Somewhat to very helpful	9 (75)
Somewhat to very unhelpful	3 (25)

[a]BIPOC: Black, Indigenous, and People of Color.

During interviews, participants described their experiences with Zamplo and other digital recovery tools, and identified their needs for future mHealth apps based on their reflections from this study. Below are findings from across these domains, focusing first on results from preliminary codebook analysis and then on 3 emergent themes from the final thematic analysis.

Codebook analysis highlighted several app features that participants repeatedly spoke highly of, prompting ideas for future mHealth apps. Favorable features included goal-setting features, life-organization features (eg, appointments, medication reminders, and to-do lists), and self-tracking and visualization features. Interviewees described beneficial mental and behavioral outcomes of interacting with such features, which included the following, in descending order of salience in the interview data: increased motivation to self-improve, feelings of accountability, greater focus on healthy habits and distraction from unhealthy habits, increased self-awareness, a sense of self-empowerment, and increased self-compassion. Functionality that was not configured in Zamplo during this study but that participants enjoyed using in other apps included gamification features (eg, rewards for progress or accumulating "points"), information and resources (eg, personally-targeted mental health tips and other educational information), community and social features (eg, group forums, chats, webinars, and media-sharing), and inspirational content (eg, regular personal affirmations and motivational quotes).

Despite the positive outcomes described by interviewees, quantitative usage metrics painted a diverse picture of engagement. A closer thematic analysis of interview data adds nuance to participants' experiences, helping contextualize our

XSL•FO
RenderX

mixed usage metrics by highlighting what participants struggled with, what they would appreciate in future tools, and potential design challenges when creating an engaging mHealth app for recovery. The following sections describe three key themes: (1) a digital journal as a touchpoint to greater recovery resources, (2) a twofold experience of Zamplo's open-ended configuration, and (3) expanding beyond substance use in recovery apps.

A Digital Journal as a Touchpoint to Greater Recovery Communities

Upon reflecting on their experiences during this app trial, participants tended to describe their needs along three categories of features, (1) personal features—journaling tools for individual self-monitoring, (2) relational features—active social spaces that enable interaction with surrounding recovery communities, and (3) informational features—frequently updating content for users to feel connected and informed about current conversations in recovery. The ideal app would bridge functionality between these 3 realms, not only providing a space for private reflection but also serving as a conduit to wider recovery ecosystems.

The first category (personal features) included goal-setting, tracking, and charting functionalities that allow participants to gain awareness and take ownership of their recovery. Such features were already configured in Zamplo during this study. The second category (relational features) included several tools that participants appreciated in other apps and would like to see integrated into a single recovery app, alongside the aforementioned personal features. These features included social networking and community spaces that allow users to share with and learn from others in recovery who are experiencing common struggles. For example, P071 requested organized peer support groups to be built into an app like Zamplo:

> *I think this is actually very important. I would actually want to have this connection with peer support groups and online community. I think that would actually be very helpful to have this online community and support groups actually around in the app.* [P071]

P032 similarly explained that their ideal recovery app would include the following:

> *…the possibility of chatting with other people experiencing the same symptoms or the same issues. Because, sometimes, it enhances the motivation, and you learn from other people's experiences.* [P032]

For relational features like these to function as participants have described, the platform would require a significant number of users who face similar challenges to join the platform so that they can begin to connect with one another. The final category (informational features) encompassed resources such as frequently-updated news postings about substance use and recovery, "tips and tricks" articles to support recovery and mental health, educational resources about substance use, inspirational stories or quotes, and personalized reading material. This type of content would provide users a sense of connectivity to the wider world of recovery. For example, P103 explained that it would be important for the app to frequently refresh with new recovery-focused content to serve as a positive pastime and increase app engagement:

> *I think I would have less anxiety, and I'd be happy to go into the app all the time, and just seeing what's new. Seeing if they added anything, or if there's any new articles or stuff to help you. Just maybe something new every day. And it's just, 'oh, look at this,' or, yeah. It just makes you happy.* [P103]

Zamplo, as it was configured during this study, did not provide this sense of connectivity with others in recovery nor did it offer personally-targeted, timely content to consume. It instead focused on providing a private digital space for participants to manage their personal recovery journeys. The minimal connection with the wider recovery world may have contributed to the mixed levels of engagement seen in quantitative usage metrics.

A Twofold Experience of Zamplo's Open-Ended Configuration

Zamplo was configured for this study with an open-ended architecture that allowed for a self-guided user experience. As such, it did not enforce that users track any specific metrics, nor did it enforce any specific types of goals to be set, or nudge user interaction according to any preset schedule. Instead, it provided participants with the means to track whichever items, set whichever goals, and schedule whichever reminders they desired. Participants were informed upon signup that they were not required to interact with Zamplo in any particular way for this study and could use the app as much or as little as they wished. This not only allowed for more naturalistic observations of usage behavior, but also surfaced a tension in participants' values regarding flexibility and control.

Zamplo's flexibility gave many participants a sense of control over their own experience. For example, P054 explained, "I liked that it was very much 'I took control of it,' and I set my own goals, and there were lots of options and reminders, if I wanted to." Similarly, P096 contrasted the flexibility of Zamplo with the rigidity of other recovery apps. Other apps often limited them to only tracking one recovery-specific goal, such as abstinence, triggering unhealthy responses when the goal is met.

> *The one [app] that was tracking my sober time, I would get too excited when it got to the month, and I'm like, "okay, let's go party." ...In this one [Zamplo], I like how I could add things and take away things. Because the other one, for me, it was just one thing, and once I reached that [goal], I felt like I had to start fresh. And I didn't see my progress for the other things, so it's like, oh, well, let's go celebrate this one. And that celebration was not always a great celebration.* [P096]

Only allowing the user to perceive their progress according to one dimension of their recovery was detrimental to P096's recovery. In contrast, Zamplo gave P096 the freedom to adapt their interface so it included a wide range of personalized goals to track.

P032 similarly described Zamplo's open-ended design favorably, explaining that they could engage with the app "at [their own] pace." P032 contrasted Zamplo with other apps that used a more strict, prescriptive approach, making them feel "pressured" if

XSL•FO
RenderX

they did not adhere to the engagement behavior enforced by the app, such as preset daily tasks to complete. Participants who appreciated the freedom to build their own experiences in Zamplo tended to describe benefits such as increased accountability, enhanced motivation, a sense of empowerment, and heightened self-awareness.

This open-ended quality of Zamplo, however, also spurred negative user experiences. Some participants described feeling overwhelmed or confused by the interface, as it did not provide the direction they would have liked. P019 described the user experience as a "free-for-all":

> *I feel like usually apps will kind of lead you through things in a certain way, and I feel like [Zamplo] was just a free-for-all. And so then it kind of just made me be like, "okay, too much going on." And I really didn't use, I don't feel like, a lot of it.* [P019]

While Zamplo's user-guided configuration gave some participants a sense of agency over their own recovery, this excerpt emphasizes that others felt burdened by the same functionality. Participants who did not appreciate Zamplo's open-ended quality often preferred a preprogrammed, prescriptive user experience.

> *It could have been easier to be like, okay, maybe "What's your goal with the app?" or "What's your goal in the next month?" Or whatever. You [the user] could say "reduce using a substance," or something. And then you could choose from a list it could prepare. ...And then it could show you, "okay, go reduce your drinks by this many," or whatever. And then it would establish some tracking starter points based on that.* [P034]

Here, P034 has ideated a user workflow that offers suggestions for recovery strategies based on personalized questions, rather than fulfilling only a passive journal-like role, as Zamplo did.

P103 additionally recalled negative experiences attempting to understand the purpose of the app: "I didn't know, like, what the meaning of the app was. Without a tutorial or, like, what am I supposed to do?" Participants did receive a step-by-step tutorial when creating an account, which included a walkthrough of each feature available to them. Still, some participants were unsure how to begin their app experience without prescribed items to track or a preset workflow to adhere to. This suggests that either the tutorial did not meet participants' needs or that they may not have engaged with it fully, possibly due to differing expectations of what a "recovery app" should provide.

A closer look at P019's interview offers an example of this mismatch in expectations. They expected a more prescriptive app design and described their experiences with a local treatment center as context for how they would expect a recovery app to function.

> *I just think that the app should guide the person, more than the person going in and really guiding it themselves. ...When I was in [anon. treatment program], they do try to keep things very basic. It's like, they structure everything for you so that you can just focus on your recovery.* [P019]

Here, P019 explained that they would prefer an app that provides a close equivalent to a formal, in-person treatment program, structuring the user experience with a top-down plan. This contrasts others' preferences for an app that allows them to set their own usage path with a multitude of options to complement in-person recovery rather than emulate it.

In summary, a tension arose from the open-ended configuration of Zamplo. The flexibility and nonprescriptive nature of Zamplo allowed some participants to feel in control of their own recovery. This led to fruitful interactions with the app's tracking and goal features, which gave rise to feelings of accountability, motivation, empowerment, and self-awareness. Meanwhile, others felt burdened by the onus of creating their own recovery regimen in the app, causing overwhelm and confusion, which may have played a role in their disengagement.

Expanding Beyond Substance Use in Recovery Apps

Finally, while the previous theme pertained to the back-end configuration of Zamplo, this theme describes the front-end subject matter available within the app. Most participants appreciated the potential to use Zamplo for purposes outside of recovery. As P096 described, Zamplo encompassed all aspects of a person's recovery journey.

> *I'm not just addiction. I'm not just mental health. I'm not just physical health. ...I am all of them, and they all impact me. Being hungry can impact my mental health, which could impact my triggers to wanting to use. It's all into one. ...This app is everything. It's not just recovery, it's not just mental health. This is a bit of everything.* [P096]

Furthermore, P054 used the goals feature to track goals not directly related to recovery, such as reading goals. They also used the goals feature to manage daily to-do items:

> *I just found it was just really easy to use and keep track of my goals, my expectations. I ended up using it for a lot of things, basically as my to-do list, and I really liked it.* [P054]

Notably, they still considered their reading goals and to-do items under the purview of "substance use" goals because they view their recovery as a holistic trajectory toward healthier daily habits. Similarly, P071 described using the fitness tracking features within Zamplo as their primary use case throughout the study, which they still considered part of their substance-use recovery regimen. The below excerpt exemplifies how this holistic app design led to a variety of tracking possibilities that all ultimately supported participants' recovery:

> *I think playing the guitar, and gratitude journaling, fitness, using medication, I think these are the things I set aside for myself in the application [Zamplo] to carry out on a daily basis. And these are the things that actually help me to avoid the usage of substances.* [P127]

However, there was a trade-off to incorporating such multifunctional, holistic tracking functionality in Zamplo. This led to an overabundance of features on the interface, each with

XSL•FO
RenderX

many potential use cases, again causing overwhelm for some participants.

> *Because I can get overwhelmed easily, and I don't like having too many options because I'm extremely indecisive, this was just way too busy for me. ...Honestly, I tried to not come into the app as frequently.* [P019]

Notably, though, those who disengaged due to feelings of overwhelm still described a preference for holistic app designs with a wide range of functionalities, rather than apps that narrowly target substance use behaviors. This preference came through in their descriptions of other apps that they have previously enjoyed and their vision of an "ideal" recovery app. Many explained that tools to assist with basic life maintenance, such as establishing daily routines or celebrating "small wins," like doing household chores, are all crucial for their recovery. However, it is essential that the digital platform provides enough clear guidance to help them navigate through the potentially overwhelming quantity of available features.

Discussion

Overview

This study resulted in the design and deployment of 3 new mHealth app features: a goal-setting feature, a craving tracker, and a meetings log. Usage analyses and interviews foregrounded quantitative and qualitative findings regarding how participants engaged with and perceived these new features and the app in general. Overall, 45.3% (24/53) of participants opened Zamplo on at least 2 separate occasions other than the required first and last days of the trial period, deeming them "active" users. These 24 active users opened Zamplo 27.1 times on average over the 42-day trial, and 45.8% (11/24) of them were still using Zamplo after 30 days.

Interviews highlighted that participants desired tools that not only act as private digital recovery journals, but also as gateways to connect with wider recovery communities and as sources of engaging and educational recovery content. A design tension also arose between prescriptive user workflows, where the app guides the user through a structured recovery plan, and open-ended platforms, where users set their own recovery regimens. Lastly, interviewees largely appreciated when apps not only focused on recovery but also included features to support them in other dimensions of their lives.

Scheibein et al [40] proposed a roadmap to achieve optimal use of digital tools in the substance use field by 2030. They identified 5 key values based on a large backcasting exercise: digital rights, evidence-based tools, user-friendliness, access or availability, and person-centeredness. They additionally warned that current digital recovery tools are heavily informed by the interests of multinational, for-profit companies, with minimal involvement from key stakeholders such as people actively struggling with substance use disorders [40]. This study has described 3 phases of a co-design and deployment process, answering this call to include end users' voices in technology design. Analysis led to several methodological insights and design implications that help to integrate the user-friendliness and person-centeredness values into recovery app development.

Reflections on Methodology

This research exemplified an end-to-end app development and testing cycle, offering a real-world case study of iterative co-design and deployment with those in recovery. As researchers strive to optimize recovery app engagement, we urge that they incorporate co-design into their methods. Valuable insights were gained during each of the 3 co-design research phases in this study. Phase 1 provided actionable takeaways for app development based on what those with recovery experience described wanting in their recovery platforms, leading to a concrete starting point for new features. In Phase 2, we gathered real-world engagement based on the features from Phase 1, revealing complex usage patterns as some users engaged and others disengaged from the app. Usage analysis then gave way to Phase 3 interviews, where nuanced design tensions came forward during one-on-one conversations with participants who could now draw upon their hands-on experience with the app.

Each phase was critical for the next phase, and they all contributed to understanding participants' perspectives on how to increase app engagement and support this population. These phases represent the beginning of a deeply iterative co-design process in which practitioners investigate end users' needs, translate their ideas into concrete tools deployed for usage, and reflect with users on the real embodiments of their original ideas. This last stage can then prompt further dialogue about future iterative designs to continue aligning more closely with users' needs.

Given the relatively low extant evidence of uptake and engagement for recovery apps, amplifying the perspectives of people with lived experience may be key to understanding why they may or may not engage with these apps. Although not all participants engaged deeply with the app during this study, still 20.8% (11/53) of all users were retained after 30 days, and 45.8% (11/24) of active users—those who went beyond minimal compliance for this study—remained engaged after 30 days. By industry standards, the typical 30-day retention rate in 2024 was 7% for all mobile apps [41] and approximately 4% for digital health apps [42]. The substantially higher retention rate in this study could be explained by participants being incentivized to take part. However, we mitigated this bias by repeatedly stating that participants are not required to interact with the app during the study to receive their incentive and are instead encouraged to use it however frequently feels helpful for them. These retention figures suggest that Zamplo features can be taken as a promising starting point for future recovery app designs. Additionally, the co-design approach may have contributed to engagement, though further controlled studies are needed to confirm this effect. This finding parallels prior literature concluding that incorporating end users' perspectives into app design can increase uptake and engagement [12]. Importantly, though, a portion of participants still disengaged from the app, necessitating further discussion of design tensions, challenges, and opportunities for future platforms.

Implications for Design

This research surfaced several design trade-offs that are crucial to consider when designing engaging mHealth apps for recovery. Interviews revealed a clear split in positive and negative experiences with Zamplo: positive experiences arose from feelings of agency and autonomy over one's own recovery, while negative experiences manifested in feelings of overwhelm and confusion. Both types of experiences resulted from the same open-ended, holistic, and flexible nature of Zamplo. As per prior research, mHealth interventions are not likely to be "one size fits all" [7]; users' needs often vary, and rigid designs are not likely to appeal to all members of the heterogeneous group of individuals in recovery. This study sheds more light on this diversity of experience and urges future designers to strike a balance between system-controlled versus user-controlled design approaches.

This tension echoes a longstanding debate in user experience research regarding the extent to which the system should impose predetermined, stepwise flows onto users, versus letting users freely set their own app workflows. While this tension is well explored in general user experience research and persuasive design domains [43], it has not been explicitly foregrounded in substance use recovery technology research, as this study has done. Indeed, this debate is particularly interesting within the recovery domain, where self-tracking technologies are often packaged as prescribed programs with fixed tracking metrics, similar to how counselors provide trusted top-down structures and routines for patients to follow. Preliminary studies in the field of human–computer interaction, however, show that app users in recovery may in fact appreciate more holistic and flexible self-tracking [25,29].

This study extends this line of inquiry by empirically demonstrating this trade-off as it relates to the recovery domain. One possible way to reconcile this tension is to design recovery apps that include both a ground-level "starter kit" with recommended features and evidence-based usage routines, while also offering additional, optional, and customizable features built on top of starter features. Users like P019, who feel overwhelmed by too much freedom, could benefit from a set of default features that reduce cognitive load and help them jumpstart their digital recovery journey. These default features could operate as a digital analogue to structured treatment programs with planned recovery pathways. For example, they could include preset goals with rigid tracking schedules, preset daily self-monitoring routines including prompts for regular check-ins and written reflections, and specific personal metrics to track on a set schedule, such as substance use quantity per day or recurring triggers. This design would need to explicitly guide the user through the interface, instructing them on how to use each feature to support their recovery, similar to a counselor's prescriptive guidance. This may be most useful for those who are new to using digital recovery apps.

Then, users like P032, who are confident to carve their own recovery pathways in a digital platform, could personalize the app to step outside the prescribed usage flows and ensure they feel in control of their recovery. This optional extended functionality could offer, for example, highly flexible goal setting with customizable goal timelines, monitoring of any chosen personal metrics, and user-determined reminders and check-in schedules to enhance self-reflection at a pace the user is comfortable with. It would be crucial for these additional features to allow tracking outside of substance-use itself to align with the present findings and the broader literature suggesting a holistic approach to recovery [29,44-46].

The distinct split between positive and negative experiences with Zamplo additionally raises questions about the characteristics of the individuals in each category. Milward et al [18] developed typologies of user engagement with harm reduction apps. They identified "trackers" who liked to track several metrics for the sole purpose of self-awareness; "cut-downers," who focused on finding a solution to their substance use and made more use of goal-setting features than self-tracking features; and "noncommitters," whose initial enthusiasm about the app quickly waned and led to disengagement.

This study found similar patterns, as illustrated in Figure 5. Several participants used Zamplo's existing tracking features but did not engage heavily with the goal-setting feature (trackers); a portion of participants displayed particularly high usage of the app in general, with special attention paid to the goal-tracking feature (cut-downers); and a portion of participants lost interest in the app after signing up for the study and never became an active user or they only engaged during the beginning of their trial period (noncommitters).

This study extends this characterization by placing more onus on designers rather than users, and suggesting that the noncommitters category does not reflect a homogenous group of people who are generally disinterested in trying to use recovery apps. We propose that this typology can be split into 2 subcategories based on the user's compatibility with the app design. One subcategory is reserved for people who are, indeed, not committed to using apps for recovery. We call this subcategory "true noncommitters." We refer to the second subcategory as "unintentional noncommitters." This group includes those who are indeed committed to finding digital recovery solutions but may lose interest in particular platforms due to ineffective designs that do not align with their nuanced recovery needs, as unpacked during this research.

Limitations and Future Work

Using existing Zamplo architecture provided us with the resources to conduct an extensive real-world app deployment study. It also provided insight into how recovery-focused features can integrate into an established mHealth platform and coexist with features not directly related to recovery. However, the preexisting Zamplo features were not the result of our co-design with end users, yet were still included in participants' experiences. This limits the internal validity of our evaluation, specifically of the co-designed features, because user experiences with those features may have been confounded by interactions with the preexisting functionalities of the platform. Additionally, parts of what participants in co-design sessions requested were not able to be fully embodied by the new co-designed features due to resource constraints and because the features had to integrate into existing Zamplo architecture.

XSL•FO
RenderX

Fraudulent participation also posed issues for this study, decreasing sample sizes in the later phases of the work. These sample sizes reduced the transferability of these findings. However, this study still highlighted several noteworthy emergent usage patterns and design tensions, despite small sample sizes. Future larger-scale research endeavors with strategies to eliminate fraudulent participation are necessary to confirm the salience of our findings.

A key finding of this study was the diversity of experience and attitudes toward using the app, as highlighted in the results of Phase 3. The small sample size of Phase 3 prevented analysis that would determine if demographics (eg, age and gender), or clinical factors (eg, recovery stage) can be linked to values and attitudes toward using a recovery app (eg, valuing autonomy versus a more prescribed user experience). Future larger-scale studies should explore such correlations in more detail. This study did reveal a subset of users inclined to feel overwhelmed by all of the available features in the Zamplo platform. Therefore, future studies using general-purpose health platforms for addictions recovery could also explore mitigating overwhelm via providing extra tutorial material.

Finally, it is important to note that this study's prime focus was capturing realistic measures of engagement with an mHealth app for recovery. However, prior work has brought into question the engagement-efficacy perspective, which assumes that higher engagement with health technology is a precursor to long term efficacy [17]. Instead, Smith et al [17] identified "productive disengagement," a phenomenon where disengaging with a health app can actually help the user in achieving their health goals. This study was unable to pinpoint every participant's exact reasons for disengagement, and instead characterized any disengagement as a negative result. As future research works to optimize engagement with recovery apps, it is important to acknowledge the engagement–efficacy assumption so that higher engagement is not always conflated with higher efficacy. Future work may benefit from investigating further into specific users who disengage with recovery apps to understand the details of their disengagement before necessarily classifying it as a negative result.

Conclusions

This study presents a detailed account of incorporating end users' design ideas into new app features to investigate engagement. We collaborated with the mHealth platform, Zamplo, to deploy 3 new app features: a goal tracker, a craving tracker, and a meeting tracker. A 6-week app trial revealed mixed engagement with the app, with 30-day retention rates substantially higher than industry benchmarks. Qualitative analysis foregrounded several mHealth features that participants perceived as valuable for their recovery. Difficult design tensions also came forward, such as balancing system control with user autonomy while mitigating cognitive load for users, as well as integrating private journal-like features into apps that also connect users to wider recovery ecosystems. This study offers early insight into the value of participatory design methods with real-world app deployment for understanding digital recovery engagement, highlighting directions for future mHealth research and design.

Abstract

Background: Mobile health (mHealth) apps are increasingly leveraged to support community health workers (CHWs) in delivering high-quality care, particularly in low- and middle-income countries. However, despite the proliferation of mHealth tools, few have been implemented at scale, partly due to limited attention to usability and acceptability among end users. In sub-Saharan Africa, mHealth tools designed for CHWs often lack systematic evaluation using validated instruments tailored to local contexts. Without such assessments, it is difficult to ensure that these tools can be integrated effectively into CHW workflows and scaled sustainably.

Objective: This study aimed to adapt and validate existing mHealth usability and acceptability assessment tools to be contextually appropriate for CHWs in Rwanda. Specifically, we sought to ensure contextual appropriateness for CHWs supporting postoperative home follow-up for women after cesarean delivery. The resulting tool was designed for use in an implementation study of a novel CHW-led mHealth app.

Methods: This study was conducted in the Kirehe district, Rwanda, from October 2022 to March 2023. We adapted 2 established tools—the mHealth App Usability Questionnaire and selected items from the Practitioner Opinion (Acceptability) Scale—and added new items that reflect core functions of the CHW-focused mHealth app. All items were translated into Kinyarwanda and simplified to align with CHWs' educational levels. We conducted a three-stage validation that consisted of (1) content validity testing with 8 local and international experts using a recommended content validity index threshold of >0.78; (2) face validity testing with 10 CHWs using a recommended face validity index threshold of ≥0.60; and (3) reliability testing using responses from 30 CHWs, with a Cronbach α coefficient of ≥0.70 indicating acceptable internal consistency.

Results: Of the 25 items assessed, 22 (88%) achieved a content validity index score of >0.78 for both clarity and relevance. The face validity index across all 22 items was 0.991, indicating strong comprehensibility and relevance to CHWs. Internal consistency was high: the Cronbach α was 0.86 for the mHealth App Usability Questionnaire items, 0.73 for the Practitioner Opinion (Acceptability) Scale items, and 0.87 for the newly developed questions. The final tool—named the Community Health

XSL•FO
RenderX

Worker mHealth Usability and Acceptability Assessment Tool—included 22 items with strong content validity, face validity, and internal reliability.

Conclusions: This study presents a rigorously adapted and validated tool for assessing mHealth usability and acceptability among CHWs in Rwanda. The Community Health Worker mHealth Usability and Acceptability Assessment Tool can guide future evaluations of mHealth interventions in similar contexts and serve as a model for localizing mHealth assessment tools in low- and middle-income country settings to ensure fit-for-purpose implementation.

KEYWORDS

mobile health; digital health; Africa; global surgery; community health workers; adaptation and validation; usability; acceptability

Introduction

Mobile health (mHealth) apps have emerged as important tools to support health care workers in delivering high-quality care, particularly in low- and middle-income countries. Over the past 2 decades, an increasing number of mHealth solutions have been developed to assist community health workers (CHWs) in performing critical tasks across a range of health interventions [1,2]. CHWs, who often have limited formal training, nonetheless play a vital role in screening, diagnosing, and managing health conditions at the community level [3]. mHealth apps targeting CHWs are typically designed to support specific workflows or interventions. However, to ensure that these tools are adopted and used effectively, it is essential to evaluate their usability and acceptability among intended users. Robust assessment can guide the refinement of interface design and core functionalities, ultimately improving user experience and the quality of care delivered. Despite the increasing deployment of CHW-focused mHealth tools, few published studies have quantitatively assessed their usability or acceptability in sub-Saharan Africa (SSA) [4-6], and to our knowledge, there are no validated quantitative tools that have been developed for this purpose.

There are several tools that assess the usability of digital interventions or mHealth apps among target users outside of CHWs. Examples of usability assessment questionnaires geared toward patients include the Mobile App Rating Scale, a tool to measure the quality of apps commonly used in the health domain [7]; the System Usability Scale, developed to assess the usability of health care innovations [8]; and the Health Information Technology Usability Evaluation Scale, a tool used to assess the usability of mHealth technologies in groups of adults living with chronic diseases [9]. Tools that assess usability among clinical providers are the Telehealth Usability Tool [10] and the mHealth App Usability Questionnaire (MAUQ) [11]. The Telehealth Usability Tool was designed to evaluate the interface quality, reliability, and satisfaction of computer-based telehealth videoconferencing software, whereas the MAUQ was developed to evaluate mHealth apps.

Evaluation of user acceptability is also a critical aspect in the development of mHealth apps. The Practitioner Opinion (Acceptability) Scale (POAS) is an example of a tool designed to evaluate the acceptability of decision aids during the development process and early evaluation stages [12]. Other examples of acceptability tools to evaluate mHealth technology include the Acceptability E-scale, [13], the technology acceptance model [14], and the User Engagement Scale [15]. However, none of these were developed to assess acceptability among CHWs.

In this paper, we describe our process of adapting existing tools to develop and validate a quantitative tool to assess CHWs' acceptability of an mHealth app and its usability. This validated tool was specifically developed to assess the usability and acceptability of a new mHealth app to support CHW-led comprehensive home-based follow-up care among women who had delivered via cesarean section in rural Rwanda.

Methods

Study Design

Between October 2022 and March 2023, we adapted and validated a tool to assess the usability and acceptability of a novel mHealth screening app in a sample of target end users (CHWs). The mHealth app supports comprehensive home-based follow-up care among women who have delivered via cesarean section. The usability and acceptability assessment tool we developed is referred to as the Community Health Worker mHealth Usability and Acceptability Assessment Tool (CHW-MUAAT).

Study Setting

This study was implemented in the Kirehe district located in Eastern Province, rural Rwanda. The Kirehe district is represented by Kirehe District Hospital, with 19 health centers and 2448 CHWs. This hospital operates under the Rwanda Ministry of Health and is supported by Inshuti Mu Buzima, a Rwandan sister organization of the US-based nongovernmental organization Partners In Health since 2005. This study was conducted as part of the study titled "mHealth - community health worker tool for comprehensive postcesarean follow-up in rural Rwanda," which was being conducted in the same area.

Selection of the Existing Tools and Initial Questions

After reviewing multiple existing tools to assess usability and acceptability of mHealth or digital health interventions, our team decided to move forward with 2 existing tools due to the relevant information they provided to our study. To assess usability among CHWs, we adapted the MAUQ for stand-alone mHealth apps, which was developed and validated in English by Zhou et al [11]. The original MAUQ comes in 4 versions depending on the type of app (interactive or stand-alone) and the target users (patients or health care providers). Given that our mHealth app is stand-alone and geared toward CHWs, we

XSL•FO
RenderX

adapted the MAUQ for stand-alone mHealth apps used by health care providers. This version of the MAUQ includes 14 questions. For acceptability, we selected the questions most relevant to our study from the POAS, validated by O'Connor and Cranney [12]; we started with 4 questions that were deemed relevant out of the 15 from this tool. In addition, we developed and added 7 usability questions; these questions were drafted by the core study team members to reflect core functions of the mHealth screening app under development. These functions were not captured in the MAUQ or POAS questions and underwent the validation steps described in subsequent sections. To assess the reading level of our assessment tool, we intentionally designed all items to meet a below 8th-grade reading level, following widely accepted best practices in health communication. This decision was guided by recommendations from the National Institutes of Health (NIH), which emphasize using plain language, short and clear sentences, and familiar vocabulary in survey instruments to promote comprehension and reduce respondent burden. These NIH guidelines support creating materials that are accessible across diverse literacy levels and help minimize misunderstanding or response error (NIH Plain Language Guidance [16]).

Translation and Adaptation

After ensuring its comprehensibility with a reading level equivalent to sixth grade, the CHW mHealth usability and acceptability assessment tool underwent a cross-cultural adaptation process, which consisted of translation into Kinyarwanda, back translation, and harmonization, as described by Beaton et al [17]. A study team member fluent in Kinyarwanda and English translated the adapted questionnaire from English into Kinyarwanda. After translation, an independent translator with skills in the health domain and who did not have access to the original version of the assessment questions translated the questions back into English. The study team and translator met to review and complete a harmonization process to help identify any ambiguity, errors, or confusion in the translated version and ensure that the tool was appropriate for the cultural context.

Validity and Reliability Testing

Validity testing comprised 2 assessments: content validity testing and face validity testing, whereas reliability was evaluated through internal consistency analysis.

Content Validity

Content validity assessed the relevancy and clarity of the tool among content experts. Eight content experts, including app developers, study team members, and clinicians, were conveniently asked to rate the relevancy and clarity of items from the CHW-MUAAT on a scale from 1 to 4 (1="not relevant" or "not clear"; 4="very relevant" or "very clear"). Content validity was established using the content validity index (CVI). The CVI was calculated using the number of experts who agreed that the item was relevant or clear (scores of 3 or 4) divided by the total number of experts. The scores for each individual item are referred to as the "item CVI." On the basis of recommended CVI thresholds from the literature [18], items with an item CVI of >0.78 were deemed content valid and remained on the survey. Those with an item CVI score of ≤0.78 were removed.

Face Validity

Face validity was established by assessing the clarity and comprehensibility of the translated tool among target end users. In total, 10 target users (CHWs) from the Kirehe district were selected at random and asked to rate the clarity and comprehensibility of the translated items on the assessment tool on a scale from 1 to 4 (1="not at all clear" or "not at all understandable"; 4="very clear" or "very understandable"). The face validity index (FVI) was calculated by dividing the number of CHWs who agreed that the item was understandable (score of 3 or 4) by the total number of CHWs (n=10). On the basis of recommendations from the literature [19], an FVI above 0.74 was considered excellent, an FVI of 0.60 to 0.74 was considered good, and an FVI of 0.54 to 0.59 was considered fair. Items with an FVI of ≥0.60 were considered acceptable and kept.

Reliability Testing

After the content and face validity testing, the adapted tool was used to assess the usability and acceptability of the mHealth app among 30 CHWs. The 30 CHWs received explanations on the use of the mHealth CHW app and were asked to respond to all questions on the app during 3 sample patient vignette role-plays led by a study team facilitator. After the sample role-play, the CHWs were asked to answer questions from the CHW-MUAAT. The full results of this assessment are presented elsewhere. For this study, we used the data from reliability testing to assess the internal consistency of the tool. The internal consistency of the tool was evaluated by calculating the Cronbach α coefficient [20]. A higher α value suggests greater internal consistency reliability, with an α value greater than 0.70 deemed to indicate good reliability [21,22].

Ethical Considerations

This tool adaptation and validation study falls under a larger study titled "mHealth - community health worker tool for comprehensive postcesarean follow-up in rural Rwanda," which received human participant ethical review approval from the Rwanda National Ethics Committee (109/RNEC/2022) and the Institutional Review Board of the Harvard Faculty of Medicine (22-1025). For the reliability testing, all CHWs provided informed consent before participating in the mHealth usability and acceptability assessments and were able to opt out of participation in the study activities. Data used in measuring validity and reliability were deidentified. Participants were compensated with 6000 Rwandan francs (approximately US $4.15) for their time and travel related to the study.

Results

The first adapted tool included 14 questions from the MAUQ, 4 POAS questions, and 7 questions added by the study team, yielding a total of 25 questions. All questions were modified for a sixth-grade reading level and underwent cross-cultural translation. The final questions for this first adaptation are presented in Table 1.

[a]MAUQ: mHealth App Usability Questionnaire.

[b]POAS: Practitioner Opinion (Acceptability) Scale.

[c]Not applicable.

A total of 10 content experts participated in the content validity survey. In total, 88% (22/25) of the items received an item CVI score of >0.78 on both the clarity and relevance scales (Table 2). Three items had an item CVI lower than this threshold and were removed. The 3 items that were removed from the first adapted set of questions were "The app does a good job of letting me know my progress," "The navigation is consistent between screens," and "I can use all the functions (such as entering information, responding to reminders, and viewing information) in the app."

All the remaining 22 items received individual FVI scores of >0.60 for clarity and relevance and, thus, were retained in the full final tool (Table 2). The FVI score for clarity across all questions was 0.991 and was the same for relevance. The full final tool is available in Table 3. The Cronbach α value was 0.86 for the 12 MAUQ usability questions, 0.73 for the 4 POAS acceptability questions, and 0.87 for the questions added by the study team, indicating the high internal consistency reliability of these questions.

Discussion

Principal Results

In this study, we adapted 2 existing tools, the MAUQ and POAS, to evaluate CHWs' perceptions of the usability and acceptability of a novel mHealth app for comprehensive home-based follow-up care among women who have delivered via cesarean section in Rwanda. Our final tool included 22 items in total: 12 (55%) out of the 15 original items from the MAUQ tool, all 4 (18%) of the items that we pulled from the POAS, and 6 (27%) new items added by our study team. The final items had high content validity among content experts and high face validity and internal reliability among CHWs.

While there is an increasing number of mHealth apps designed to support CHWs across SSA, very few are operating at a large scale and beyond isolated research settings [2,23,24]. One of the key barriers to scale-up is the limited understanding of whether these tools are perceived as usable and acceptable by the CHWs expected to adopt them. Without sufficient usability and acceptability, even well-designed tools are unlikely to integrate effectively into CHW workflows. Although a few studies in SSA have examined these dimensions among CHWs [2,4-6], most have not used adapted or validated tools, limiting the reliability and comparability of their findings. A recent review found that 70% of researcher-developed usability questionnaires for mHealth apps were not validated—and those validated were not tailored to the community health context [25]. Validated assessment frameworks are critical to draw robust conclusions about user experience and determining the potential for mHealth tools to be well integrated into routine practice.

This quantitative CHW-MUAAT scale provides a standardized, scalable way to summarize usability and acceptability constructs, which facilitates comparison of potential digital tools in one environment or of the functionality of a single tool in different contexts [26]. However, complementary qualitative data can offer deeper insights into the contextual factors that shape CHW perceptions of usability or acceptability. For example, a mixed methods study identified that CHWs in Uganda had high rates of digital health acceptance but low digital tool use due to low smartphone ownership [27]; similarly, a study of *YendaNafe*, a mobile app to support CHW activities in Malawi, found an overall positive acceptance of the app but that there were several facilitators of and barriers to actual app use [28]. For this study, our qualitative results indicated general acceptability and emphasized that strong CHW-patient relationships and trust were needed for successful implementation (full results available elsewhere [29]).

To meaningfully inform the integration of an mHealth app into CHWs' workflows, usability and acceptability assessments must be tailored to the local context and to the needs and capacities of end users. In our study, this required careful linguistic and cognitive adaptation of existing measurement tools. Given that most CHWs in Rwanda have completed only primary school education, our team revised the wording of several items to ensure that they were easily understandable. For example, the original item "There is a high probability that using this strategy may cause or result in more benefit than harm" was simplified to "I think using this mHealth app will be more helpful than hurtful" [30]. Additionally, all items were translated into Kinyarwanda, the primary language spoken by CHWs, with attention to clarity and cultural appropriateness.

Beyond linguistic adaptation, we also modified the content of existing tools to better capture usability and acceptability as related to the specific task—home-based follow-up care after cesarean delivery. This included rewording items from the MAUQ and POAS tools and adding step-specific questions relevant to CHWs' real-world experience. For example, questions about ease of logging into the app were added given that many CHWs have limited experience with smartphones. This consideration is important in Rwanda, where, as of 2024, although 80% of households own a mobile phone, only 34% own a smartphone [31]. By demonstrating a structured approach to adapting and contextualizing usability and acceptability assessment tools, this study offers both a practical instrument and a replicable methodology for future CHW-focused mHealth evaluations in similar settings across the region.

This instrument can be adapted for other teams interested in assessing the usability and acceptability of a particular CHW mHealth tool with appropriate adaptation and validation. First, they may need to identify usability questions tailored to community health interventions, similarly to how our team added 7 usability questions specific to our postcesarean monitoring app. These questions will need to undergo reliability and validity assessments. The full tool should then be piloted in their settings, whereas smaller sample sizes may be warranted given the baseline work presented in this paper.

Limitations

We acknowledge that the adaptation and validation of the tool has some limitations that should be considered. First, this study had a small sample size of content experts and CHWs. Because of the overall high scores and consistent conclusions, we are confident in the validity of the final tool developed, but future validation studies will likely need larger sample sizes if there is more variability in participant responses. Second, this tool focuses on a quantitative assessment that cannot pick up nuanced responses. Our final evaluation includes the quantitative responses collected using this tool during the usability and acceptability testing of the app. However, we do believe that these standardized assessments can help those evaluating mHealth apps identify areas for improvement and test against prespecified targets to determine whether the mHealth app is ready for broader use. Finally, this tool was designed for a specific intervention—a mobile phone app developed for CHWs to use during the home visit follow-up of women who delivered via cesarean section—and was only validated in the Kinyarwanda language. Other research groups should proceed cautiously and likely conduct their own validation studies when applying this tool to a different intervention or in a different language.

Conclusions

Our team is using the final tool as a core component of evaluating an mHealth app used by CHWs to support women

XSL•FO
RenderX

after cesarean delivery. The processes and tool described in this paper serve as a model for others conducting CHW usability and acceptability assessments of mHealth apps in SSA. Such assessments will be critical for moving toward better integration of innovative solutions into CHW activities.

Acknowledgments

The study team acknowledges the support of Partners In Health/Inshuti Mu Buzima; Kirehe District Hospital; and Mulindi, Nasho, and Mushikiri Health Centers' leadership and the community health workers for their voluntary participation. The authors declare the use of generative artificial intelligence (GenAI) in the research and writing process. According to the Generative Artificial Intelligence Delegation Taxonomy (2025), limited proofreading and editing tasks were delegated to GenAI tools under full human supervision. The GenAI tool used was ChatGPT (OpenAI). Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to restrictions on data sharing in accordance with the Rwanda Data Protection and Privacy Law but are available from the corresponding author on reasonable request.

Funding

This study is part of a study funded by National Institutes of Health grant NIH/FIC-5R21HD103052-02. Author SN is supported by the Fogarty International Center and National Institute of Mental Health of the National Institutes of Health under award D43 TW010543.

Authors' Contributions

Conceptualization: SN, JN, EHE, BH-G, VKC
Data curation: JN, MK, SN, EHE
Funding acquisition: BH-G
Methodology: SN, JN, EHE, BH-G, VKC
Supervision: BH-G, VKC
Writing—original draft: JN
Writing—review and editing: JN, SN, EHE, MK, AB, RRF, NB, LB, BH-G, VKC
BH-G and VKC were principal investigators. All authors reviewed and approved of the final version of the manuscript.

Abstract

Background: Wearable devices with real-time feedback (WRFs) provide increasing opportunities to enhance physical activity and improve rehabilitation through collecting and processing health-related data. Real-time feedback (RTF) from the device is expected to result in a more dynamic, coordinated, and synchronous rhythmic activity, defined as step-by-step movements mediated by the real-time heart rate feedback. However, age-specific characteristics in the user engagement with WRFs integrating real-time audio feedback have largely remained unexplored.

Objective: This study explores the lived experiences of older adults using wearables with RTF to uncover motivations, aspirations, and hindering factors in their engagement with WRFs in rhythmic activity. The study explores narratives that older adults articulate in their previous use of wearables for physical activity, their experiences with WRFs during rhythmic activity, and their meaning-making of the interactive features enhancing the synchronization of the movement during rhythmic activity.

Methods: The study was conducted as a qualitative interview study with 18 older adults who used a WRF for rhythmic activity during a 3-week period in their home environment. The wearable used in the study is a chest-band sensor device that helps users to synchronize their steps with their heartbeat through the provision of real-time audio feedback. The material consists of semistructured interviews before and after using the device. Material from the semistructured interviews was analyzed with an interpretative phenomenological analysis method.

Results: The study identified four main themes characterizing older adults' lived experiences with wearables, which are (1) use of wearable technologies without RTF in daily life, (2) embodied rhythmic negotiation with RTF, (3) interpretation of health data with RTF, and (4) temporal trajectories of device engagement with RTF. Older adults demonstrated intentional distancing from wearable technologies rather than simple disuse, prioritizing authentic bodily experiences over external validation. Their engagement was fundamentally relational, mediated through trusted social networks, and required dialogical support for data interpretation. Device-guided movement synchronization created contextually situated challenges that varied significantly based on environmental demands, individual bodily capacity, and exercise routines. Extended temporal engagement transformed participants' relationships with the technology from initial disruption to potential integration, with RTF serving as a bridge toward enhanced embodied awareness when carefully designed.

Conclusions: The study concludes that RTF from the device can enhance synchronization and bodily awareness, but meaningful engagement requires adaptive designs that respect older adults' authentic movement practices, accommodate their relational approach to technology validation, and allow sufficient time for embodied competency development.

Introduction

Background

Physical activity (PA) is an important predictor for active and healthy aging; yet, few older adults meet the recommended levels of PA [1]. Wearable devices with real-time feedback (WRFs) having sensors provide increasing opportunities to enhance PA through collecting and processing health-related data [2,3]. Despite their potential, the long-term user engagement with wearables remains a challenge [4-6]. In particular, age-specific characteristics in the user engagement with interactive wearables with real-time feedback (RTF) have remained largely unexplored.

This study explores the use of wearables with and without RTF to uncover the lived experiences of older adults in their engagement with interactive wearables. WRFs can be defined as body-worn technologies that implement technologies, such as sensors, to measure biomedical information, combined with modalities, such as haptic or auditory feedback, that help users to adjust the movement to improve the performance in PA [7]. Rhythmic activity can be defined as a form of PA that incorporates elements such as auditory feedback, music, and social interaction, which involve coordinated movements synchronized with music [8-10]. In this study, we define rhythmic activity as a step-by-step movement (eg, walking or running) that is mediated by a device-guided synchronization of step and heart rate.

Older adults, defined as an age group of 65 years and older, are considered an important user group of WRFs due to the potential of wearables to improve PA, rehabilitation, and cardiovascular health [1,11-14]. Due to demographic changes accompanied by population aging, wearables as digital health interventions are expected to contribute to health promotion and prevention of disease among this demographic [15]. However, the adherence with these interventions still remains a challenge [4-6]. Older adults' adherence with wearables is mediated by their health, motivations for PA, and digital skill literacy, which can impact the use of wearables that require dexterity, mobility, or vision [16,17]. Older adults emphasize enjoyment of social interaction as a motivation to be physically active [1], and wearables can enhance this through the provision of visual or auditory feedback [12]. The perceived appeal of visual or auditory feedback, however, is individual and mediated by the lived experiences in later life. This suggests that affordances embedded in wearables are not directed only toward improving performance, but also delivering a sense of self-awareness [13]. Considering the individual differences in older adults' motivations, it becomes important to recognize their lived experiences when exploring their adherence to WRFs.

The aim of this study is to explore the lived experiences of older adults using wearables with RTF in rhythmic activity. The study explores narratives that older adults articulate in their previous use of wearables for PA, their experiences with WRFs during rhythmic activity, and their meaning-making of the interactive features enhancing the synchronization of the movement during rhythmic activity.

Wearables With RTF

Wearable technologies are designed and used for enhancing PA in health promotion, preventative health, and treatment of health conditions [18]. As *self-care technologies*, wearables allow the user to take responsibility for managing their own health independently, without external intervention from the health care provider [15,19,20]. As a *medical technology*, wearables can be used before medical diagnosis to monitor PA levels, and detect and predict the onset of clinical conditions [21].

Wearable technologies include a variety of applications, such as smart watches and chest bands, and these technologies integrate features, such as instructions, self-monitoring, and reminders, along with customizable options [22,23]. These interactive features, such as goal setting, feedback provision, and motivation tracking, are increasingly implemented in day-to-day applications [23]. RTF refers to an interaction mechanism that provides haptic, auditory, or visual feedback to the user simultaneously with the user's movement, instead of after the movement or activity has ended [2,3]. Machine learning techniques have enabled accurate and rapid human gesture recognition, providing RTF to users [24]. WRFs have been investigated among athletes in the prevention of injuries, improvements of performance [2,25], as well as in rehabilitation [26]. For older adults, RTF has been shown as a preferred feature in wearables [11]. In comparison to other interactive features, RTF, as a rather novel feature, has nevertheless been less implemented in commercially available wearables [2].

RTF enables reactions from the user while the action or movement is ongoing. Auditory feedback allows users to be observant of the environment and fits into more dynamic settings compared with both visual and tactile guidance [27]. Through sound interaction, users can coordinate and stabilize movements with internal or external imposed rhythms [28]. Auditory feedback can be used in a variety of physical activities, ranging from guiding speed to correct movements [25], supporting coupling steps and breathing in day-to-day running exercises [27], to guiding static breathing exercises [29]. Beat-by-beat stepping to the heart rate has shown improved heart function in athletes; however, without assessing motivational aspects of this interaction [30]. As an alternative to the auditory cues, the use of music can increase motivation and engagement in cardiovascular rehabilitation [31].

Factors Influencing Adherence With Wearables Among Older Adults

Wearables are accessible and easy to use, but the adherence, defined as long-term user acceptance and engagement with the device, remains a challenge [4-6]. The ownership of wearables is defined by sociodemographic factors, such as age and gender. Younger groups with higher levels of education and full-time employment are more likely to own a wearable compared with other demographic groups [32]. Older adults' motivations for using a wearable may also significantly differ from other age cohorts regarding the perceived value and ease-of-use of the device [11,14,33-35].

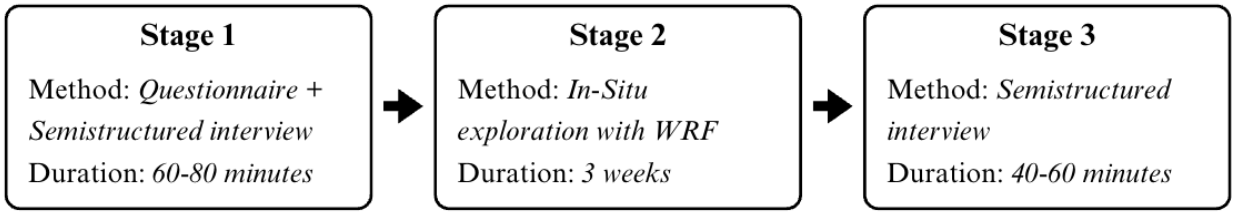
Long-term adherence to wearables is determined by a combination of individual motivation, ease-of-use, and perceived

XSL•FO
RenderX

value of the wearable, which subsequently predicts whether or not the device will be integrated into the user's life [11,33]. Older adults must be motivated by the usefulness of the device and its added value to PA [11,36]. Formal and informal support and guidance in having access to the device and continuing its use are connected to long-term adoption [37]. These individual factors are expected to differ between older adults, resulting in heterogeneous use of wearables depending on various individual and social determinants [10,16,17].

Emotional, sensory, and social influences also impact the user engagement with wearables [13,38,39]. Long-term attachment with wearables requires that these devices elicit positive emotional responses among users [40]. When wearables are framed as an assistive technology that aims to compensate for age-related functional or cognitive losses, older adults might abandon these devices due to (negative) user images [36]. Wearable devices can be perceived as motivating or condescending depending on how freely older adults can make autonomous choices about PA [34].

Accordingly, older adults face barriers to wearable adoption, including issues about usability, affordability, and accessibility, which can lead to social isolation and marginalization from digital health innovations [41]. At the same time, digital technologies offer significant opportunities for older adults, who often have more leisure time and are financially independent, to seek health-related information and maintain self-care [15,42]. Fewer phenomenological studies are focused on exploring older adults' experiences with rather novel wearable technologies in their home environments. This methodological approach allows us to capture the essence of subjective experiences and the perceived value they derive from using wearables through first-person descriptions [41-44] and the meanings they attribute to the interactions with wearables [15,45]. The research questions (RQs) are the following:



- RQ1: What kind of narratives do older adults articulate in the use of wearables for PA?
- RQ2: How do older adults experience the use of wearables with RTF in rhythmic activity?
- RQ3: What kind of meanings do older adults associate with the interactive features of a WRF during rhythmic activity?

Methods

Study Procedure

This study consisted of three stages: (1) semistructured interview and a questionnaire before using WRF, (2) a 3-week use of WRF for PA (referred to as in-situ study), and (3) a semistructured interview after using WRF. Figure 1 presents the method and duration of each stage.

Figure 1. Method and duration for each study stage.

In the first stage, we conducted a semistructured interview for participants to investigate their motivation for PA, self-perceived health and well-being, previous experience with technologies, and previous interactions with wearables for PA. Participants were also given a questionnaire measuring their PA level, self-perceived health, and sociodemographic characteristics.

In the second stage, participants were asked to use a WRF for a 3-week period in their home environment. They were asked to use the device at least 3 times per week during their PA routines, including any rhythmic activity, such as walking, running, or jogging. Each participant was shown how to use the device, and the device was set up and connected to their mobile phones. They also received detailed written instructions for using the device. A 3-week period for in-situ study was selected to ensure the feasibility of the procedure as a common period in digital health intervention studies [46].

In the third stage, we conducted semi-interviews to explore participants' lived experiences with the device, focusing on their self-perceived perceptions of the device and its impact on motivation and adherence with rhythmic activity.

Recruitment of Participants

Participants in this study were recruited through convenience sampling at the Swedish School of Sport and Health Sciences. An open invitation was distributed to those who attended the physical exercise sessions 3 times a week at the Swedish School of Sport and Health Sciences. Since the WRF device was originally designed for athletes to improve their performance, we recruited physically active older adults to ensure that the device was considered meaningful and safe for the user group to allow a phenomenological approach to their experiences [47,48]. Other inclusion criteria were (1) participants aged older than 65 years, (2) able to exercise independently without assistive devices, (3) own a mobile phone that can download the app and could carry the phone during PA, (4) able to adequately see and hear (with or without a hearing aid) the wearable devices' RTF, and (5) able to read and speak English to follow the WRF's instructions.

In total, 21 older adults were recruited, and 18 of them completed all 3 stages in the study. The sample size was determined based on the principles of qualitative research and purposive sampling, where having 20 participants is often

XSL•FO
RenderX

considered a saturation point after which little or no new information is generated from 1 participant group [49].

Data collection

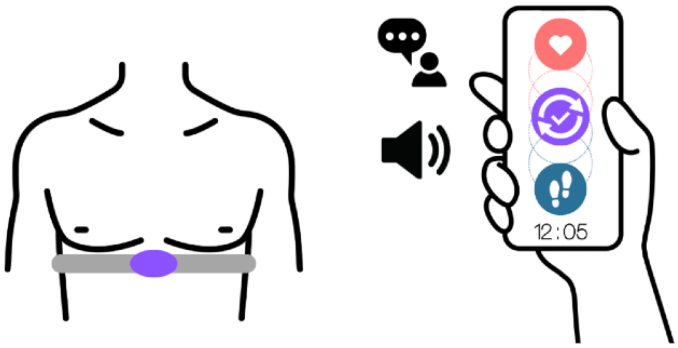
Questionnaires

At the beginning of this study, a questionnaire designed and based on guidelines from the Swedish National Board of Health and Welfare [50,51] was distributed for older adults to subjectively assess their health status and PA (Multimedia Appendix 1). Weekly PA time with multiple-choice questions for both high- and low-intensity activities was reported. Self-perceived health is measured using a 5-point scale covering self-perceived physical health. Other information includes age, gender, marital and family status, living arrangements, and finally, a section for additional comments. In this study, the questionnaire results were used as background information on the participants' health and PA.

Semistructured Interview

We conducted 2 rounds of semistructured interviews with the participants before and after they used a WRF for 3 weeks. All interviews, lasting approximately 45-60 minutes, were audio-recorded and later transcribed for analysis. Interviews were conducted by 2 researchers, and they were collected as individual in-person interviews. Interview guidelines were prepared for both interviews to ensure that the procedure was similar in all interviews (Multimedia Appendices 2 and 3).

In the first round of interviews, participants were asked about their life situations and daily routines in PA, including questions about their PA patterns, motivations, challenges, and perceived health. Questions were asked about their previous use of digital health technologies and wearables. For those who had used wearables previously, we asked about the contexts, benefits, and challenges of wearables use, while nonusers of wearables were asked about their expectations and willingness to adopt such technologies. This interview also touched upon the social aspects of wearables for PA, including preferences for group exercise and peer advice on technology adoption. In this round of interviews, we gathered comprehensive qualitative data about participants' relationships with both PA and technology (Multimedia Appendix 2).



After participants had used the WRF for 3 weeks, they attended the second round of interviews. Participants were asked about their experiences, perceptions, and attitudes toward the device based on their usage of it in rhythmic activity (walking, jogging, or running). Participants were encouraged to reflect in detail on their interactions with the device, including possible challenges. Questions relating to user experience sought to understand participants' motivations and emotional responses toward WRF and capture the subjective, contextualized characteristics of their engagement. We probed participants to evaluate the RTF and whether or not it was seen as supportive. Usability-focused questions assessed the ease of use and technical barriers. Finally, we addressed acceptance and future use of WRFs to inspect their openness to long-term adoption for more advanced interactions, such as conversational features or personalized feedback mechanisms (Multimedia Appendix 3).

In-Situ Study of the Device

In-situ study is valuable for exploring health-related experiences because it honors participants' situated knowledge and lived contexts [52,53]. Engaging with the embodied and sensory dimensions helps to reveal nuanced insights into how contextual factors shape health and well-being [54,55]. Moreover, this method allows participants to actively take control of their experiences and foster their agency [56,57]. This aligns with our intention to offer participants more flexibility and autonomy throughout the study.

The WRF used in this study, Counterpace (Pulson Inc), is a commercially available novel wearable that guides wearers to step precisely between heartbeats during rhythmic activity. Its chest-worn electrocardiography sensor detects the heart state (contract or relax), and an accelerometer detects the walking state (stepping). The connected mobile app provides visual information (step rate, heart rate, and synchronization time and percentage). It also provides voice instructions and metronome beats for wearers (Figure 2). By synchronizing step pacing with heartbeats, the device promotes a step-by-step movement that we define as *rhythmic activity* in this study. There are 2 main reasons why this device was chosen. First, this WRF is developed for rhythmic activity, which is expected to positively influence cardiovascular health [30], with possibly greater benefits for older adults due to increased vascular stiffness [58]. However, its usage and benefits for older adults remain underexplored. Second, although this WRF was originally developed for elite runners and high-performance training, its design has not considered accessibility or inclusivity.

Figure 2. Schematic diagram of the WRF—it consists of a chest-worn heart rate and step rate sensors and a mobile app, which provides both real-time visual and auditory feedback. WRF: wearable device with real-time feedback.

XSL•FO
RenderX

By introducing this technology to older adults, we aim to understand whether its potential benefits could be motivating and meaningful for this population, and to uncover the specific challenges they encounter in using it. Their activity and heart rate were recorded by the mobile app and stored in an anonymized format on a cloud-based service. Participants were encouraged to contact the researchers for technical support throughout the study.

Participants

Of the 21 recruited participants, 18 completed all stages of the study. Table 1 presents their sociodemographic characteristics. The majority (11/18) were between the ages of 70-75 years, with 3 participants aged 66-67 years, and 1 participant older than 80 years, with a mean age of 72.1 years. Most participants were females (12/18). For the PA level, the majority (15/18) reported 90 minutes or more of high-intensity activity per week, with 2 participants reporting an intermediate level (30-89 minutes), and only 1 reported a low level (0-30 minutes). Most participants (10/18) also engaged in 90 minutes or more of low-intensity PA per week. Moreover, 6 participants reported high perceived physical health (scores 1-2), while 4 reported low perceived physical health (scores 5-6).

Table 1. Participants' sociodemographic characteristics, including age, gender, physical activity level, and perceived health (n=18).

ID	Age (y)	Sex	High-intensity PA[a] level (minutes per week)	Low-intensity PA level (minutes per week)	Perceived physical health[b] (score 1-6)
P1	70	Female	≥120	30-89	High
P2	74	Male	90-119	30-89	Medium
P3	70	Female	90-119	30-89	High
P4	70	Male	≥120	90-119	Medium
P5	78	Female	≥120	≥120	Low
P6	72	Male	90-119	30-89	Medium
P7	76	Male	30-89	30-89	Medium
P8	71	Female	≥120	0-30	Medium
P9	82	Male	0-30	30-89	Medium
P10	70	Female	90-119	90-119	Medium
P11	70	Female	90-119	30-89	Medium
P12	72	Male	≥120	≥120	High
P13	78	Female	≥120	≥120	High
P14	72	Female	30-89	90-119	Medium
P15	67	Female	≥120	90-119	High
P16	66	Female	≥120	≥120	Low
P17	72	Female	≥120	90-119	Low
P18	67	Female	90-119	≥120	Low

[a]PA: physical activity.

[b]Perceived physical health was assessed by asking participants, "How satisfied are you with your health?" using a 6-point Likert scale, where 1 indicated very satisfied, and 6 indicated not satisfied at all. The responses were grouped as follows: high=scores 1-2, medium=scores 3-4, and low=scores 5-6.

Analytical Approach

This study used a phenomenologically informed qualitative approach, drawing on the principles of interpretative phenomenological analysis (IPA) [47,59] to explore how older adults make sense of their experiences with wearable technology in PA. IPA is particularly suited to examining how individuals interpret, reflect on, and assign meaning to personally significant experiences, with an emphasis on embodiment, temporality, and the situated nature of meaning-making.

While the early stages of the analysis were guided by a thematic analysis conducted by 3 researchers to navigate a rather large and diverse dataset [60,61], the final interpretative process was anchored in phenomenological inquiry. The goal was not simply to identify recurring patterns but to understand participants' lived experiences in depth, including how they perceived, emotionally responded to, and negotiated the role of wearable devices in their embodied PA routines.

The analysis followed a recursive and idiographic process, beginning with repeated readings of each interview transcript to immerse in the participants' narratives. After preliminary notes were made, segments that revealed how participants made sense of their relationship with WRF were identified and grouped. These segments were later interpreted within the broader biographical, social, and emotional context, maintaining an interpretative stance that sought to balance empathic understanding with critical reflection, a process central to IPA's double hermeneutic process. Although initial thematic groupings

XSL•FO
RenderX

were constructed, these were reevaluated through a phenomenological lens to ensure that the final themes captured the depth, nuance, and individuality of participants' meaning-making. Particular attention was paid to heterogeneity among the narratives articulated by older adults, not as demographic variance, but as diverse experiential positions shaped by bodily awareness, social scaffolding, emotional responses, and contextual life circumstances. The final themes represent not only recurring patterns but rich, interpretative accounts of how wearable technologies were encountered, negotiated, incorporated, or even resisted in older adults' daily lives.

Ethical Considerations

The research has been approved by the Swedish Ethical Review Authority (references 2023-00426-01 and 2024-06934-01). All participants gave informed verbal and written consent for participation in the study and for publication of anonymized extractions from the data. Before participants signed the informed consent, they were given both written and verbal information about the effects of adapting this device in their PA routines and potential risks in participating in the study. Participants were given the possibility to ask questions and withdraw from the study at any time. The privacy and confidentiality of participants were protected by giving all participants a pseudonym (numeric ID) that was used in the analysis and reporting of the results. Participants were given a small financial compensation of a gift card worth 500 SEK (US $54) after they completed their participation in the study. The amount of financial compensation was not specified in the recruitment material.

Results

Overview

The analysis revealed four superordinate themes: (1) use of wearable technologies without RTF in daily life, (2) embodied rhythmic negotiation with RTF, (3) interpretation of health data with RTF, and (4) temporal trajectories of device engagement with RTF (Table 2). The results capture the embodied, temporal, and situated nature of participants' meaning-making processes, revealing how relationships with technology evolved. A detailed analysis table can be found in Multimedia Appendix 4. The findings demonstrate the depth and heterogeneity of lived experiences, showing how wearable adoption is deeply personal and contextual, shaped by participants' ongoing negotiation between technological mediation and their intuitive, embodied understanding of PA.

Table 2. Themes from the interpretative phenomenological analysis.

Superordinate theme	Subordinate theme
Use of wearables without RTF[a] in daily life	• Embodied autonomy and resistance to digital mediation • Contextual and temporal meaning-making • Tensions and ambivalent emotional responses
Wearables with RTF: embodied rhythmic negotiation	• Disrupted natural flow • Learning and guided transformation • Raising bodily awareness through real-time multisensory feedback
Wearables with RTF: interpretation of data	• Relational meaning-making of health data • Technological barriers hindering PA enhancement
Wearables with RTF: temporal trajectories of device engagement	• Disruption and emerging connection in limited engagement • Awareness and growth in moderate engagement • From discipline to integration in extended engagement

[a]RTF: real-time feedback.

Use of Wearables Without RTF in Daily Life

Overview

Participants expressed diverse narratives with wearable technologies, shaped by personal values, bodily autonomy, and lived experience. Many resisted using digital tools, such as tracking apps, prioritizing internal bodily awareness over external data. Engagement was also influenced by social networks and emotional responses, such as stress or pressure. Technology use reflected intentional choices rooted in identity, context, and trust.

Embodied Autonomy and Resistance to Digital Mediation

The lived experience of wearable engagement was characterized by participants' assertion toward embodied autonomy over digital health mediation. This theme represents a profound stance where participants actively resisted and defended their authentic relationship with their bodies against what is perceived as technological intrusion. This theme emphasizes that participants' adoption of wearables goes beyond simple preference, revealing a deeply held commitment to preserving their agency and embodied experience in health and wellness practices.

Most participants owned one or more wearables but deliberately remained disconnected from them, manifesting as "ownership without utilization," where possession of the technology coexisted with intentional non-engagement. For instance, in P2's statement, we see more than simple disuse; we see intentional distancing from technology.

> *I have a smartwatch, but I do not want to use it during physical activity. I keep it somewhere at home.* [P2, male, 74 years]

XSL•FO
RenderX

The way participants physically removed themselves from their devices reflects a conscious choice to make the technology irrelevant in their daily lives, expressing a more profound desire to protect their genuine, lived experience of the body and to maintain psychological boundaries against letting technology shape their bodily awareness.

The experience of external pressure from family, friends, or PA instructors to adopt wearables revealed another dimension of resistance. One participant's steadfast position of remaining uninterested was evident as he was,

> *…uninterested in adopting wearables, even though my son uses a smartwatch and tries to persuade me to wear it too. I do not think it is that important to know how many steps (I took during my walks) because I already feel it roughly.* [P4, male, 70 years]

This illuminated how this resistance was not rooted in inaccessibility, but rather in a principled stance about the characteristics of health monitoring. This resistance is grounded in an understanding that external validation of bodily states has less value compared to their own physical experience.

For some participants, PA was experienced as unencumbered bodily engagement, where additional equipment was perceived as interference with pure movement. One participant articulated this essence with particular clarity:

> *For me, that is why I like jogging and running. I do not want... (to use wearables). It should be easy to train my body... It should be just as easy as possible to move around.* [P10, female, 70 years]

Her lived experience revealed how wearable technology was perceived as disrupting the unmediated nature of exercise. Participants' preference for exercise as "easy" was not about avoiding difficulty, but about maintaining a natural and straightforward connection between mind and body during exercise, suggesting that participants viewed their rejection of wearables as a protective measure for something fundamental to their identity and well-being.

Moreover, the lived experience of health monitoring was characterized by participants' profound trust in their own bodily awareness over technological feedback, revealing a sense of self-awareness grounded in direct physical experience rather than external measurement. One participant explained:

> *I have an Apple Watch, which I do not use much... I look at my heart rate because of the type of exercise I do. But I am kind of structured anyway.* [P14, female, 72 years]

Her experience illuminated how participants privileged their embodied and intuitive understanding of their bodies over external technological validation. Their narrative suggested that they possessed an internal system for understanding their physical needs and responses, rendering external monitoring redundant. This represented not only the rejection of health monitoring but also a commitment to internally generated, experientially based health awareness that participants trusted more than digital data.

Contextual and Temporal Meaning-Making

Participants' engagement with wearables unfolded as profoundly contextual and temporal, where meaning and utility shifted across different life circumstances and personal preferences. Participants' interactions with technology were not static, but a dynamic process of meaning-making that they continually reflected upon in relation to contextual needs and values. The temporal dimension of this engagement also suggests that relationships with wearable technology were biographically embedded within participants' life stories and subject to reinterpretation over time.

Contextually, the technology preference emerges through participants' definition of what "useful health monitoring" entails, revealing highly individualized criteria. One participant articulated:

> *(I found) a basic step-counter in the form of a phone-based application sufficient to track most basic physical activities.* [P1, female, 70 years]

Her use of the word "sufficient" was particularly intriguing, which shows that she had developed precise measurements for what constitutes adequate, allowing her to be free from external recommendations or marketing messages about optimal health tracking. This preference revealed how participants proactively set their own boundaries around technological complexity and determined what digital tools aligned with their technological sophistication, necessity, and manageability.

Additionally, selective engagement with personal data interpretation emerged as participants demonstrated discernment about which aspects of wearable technology resonated with their personal understanding of health and movement. One participant described his experience:

> *(During walking and running) It is fun to see how far you have gone, how fast you have gone, what kind of mileage you have got…* [P4, male, 70 years]

This illustrates how enjoyment emerged from specific data points that connected with his personal measurement of a meaningful activity. His emphasis on "fun" shows that the engagement was not just driven by arbitrary fitness imperatives but by his intrinsic interests in tracking and inquisitiveness in his performance. This selective engagement demonstrates how participants acted as curators of their technological experience by choosing to interact with elements that enhance their PA.

On the negative side, abandonment or pause of usage occurred due to temporal change in their relationships with wearables, disclosing how the purpose and utility of these devices were subject to changing life circumstances, which vary from the loss of family members, injury, chronic diseases, relocation, and so on. Another participant described how her usage of wearables shifted over time:

> *I used to have one (Garmin watch) many years ago when I was running. It was useful then, but now I do not use it anymore.* [P13, female, 78 years]

The phrase "*it was useful then*" implies that usefulness was not an inherent property of the technology, but rather a mixture of the device's capabilities and the participant's needs at that

XSL•FO
RenderX

particular period in her life. Ultimately, the disengagement with wearable devices was the natural evolution over time, and could not be indicative of their usability or utility.

Finally, we discovered a technological curiosity among participants who have not tried any wearable devices, as evidenced by their openness to digital health tools, particularly those that offer well-structured guidance for PA. A participant expressed that,

> *I appreciate and I believe in technology. And I had tried several fitness apps previously…* [P3, female, 70 years]

This highlights a broader exploratory relationship with digital health resources. The experimental approach to "try and find" a new tool indicated that participants do not regard technology adoption as a firm commitment to 1 tool, thereby retaining control over their engagement. This sense of curiosity also reflects active meaning-making, as participants need various technologies and can identify those that resonate with them, rather than simply consuming them passively.

Tensions or Ambivalent Emotional Responses

The use of wearables among older adults was significantly influenced by their social and emotional aspects. This subtheme illuminated the social nature of technology adoption among this demographic, which was often embedded within and mediated through personal networks and communities. Similarly, their engagement was marked by complex, often conflicting feelings, demonstrating that wearables are not a neutral tool but an emotionally charged artefact that can have a profound impact on participants' sense of self and their relationship with their bodies.

The social dimension of wearable adoption was notably influenced by participants' trust toward others, who served as mediators of acceptance and attachment. One participant described how her wearable usage began through professional guidance:

> *I got to know about my smart ring from a health engineer. She is also very skilled in various aspects of health. And she was the one who suggested this ring.* [P17, female, 72 years]

P17's emphasis on the health engineer's expertise suggested that this referral carried weight in her decision-making because it came from individuals whose judgment she believed. The technology gained legitimacy through respected social connections, and at the same time, this mediation represented not simply an information transfer but also the validation of technological benefits.

Some participants also mentioned attending webinars and lectures on new technologies, suggesting that older adults' technology adoption was facilitated through community-based learning environments where they could explore within supportive contexts. This furthermore shows that older adults' engagement with wearables was fundamentally relational rather than individualistic. This social scaffolding appeared crucial for older adults who might otherwise feel intimidated by or skeptical of wearable technology, providing both practical guidance and emotional support for technology exploration.

Participants demonstrated remarkable emotional awareness in expressing these complex relationships with wearables. We found that accessing and tracking health data is a double-edged sword, raising paradoxical feelings. Participants, such as P6 (male, 72 years) and P15 (female, 67 years), reported feeling negative emotions, including stress, confusion, and anxiety, after noticing an unexpected decline in their PA levels. Their experience exemplifies how data can disrupt their perceived well-being. More explicitly, P15's experience illuminated the tension between the potential benefits and its emotional costs:

> *I have a step calculator (on the phone). But I do not want to check it all the time. It is competitive and stressful... I think that is stressful.* [P15, female, 67 years]

P15's experience revealed how the pressure of goal-oriented tracking conflicted with her authentic relationship to PA, leading her to limit her engagement. The repetition of "stressful" in her statement emphasized that constant monitoring could hinder her view of the technologies. Her description of tracking as "competitive" suggested that it is hard to disconnect the quantitative data from external standards, such as suggested steps per day, even though well-being should be very individual and personalized.

Wearables With RTF: Embodied Rhythmic Negotiation

Overview

Participants experienced RTF as both disruptive and transformative. While initial use challenged authentic movement patterns, some developed new bodily awareness. Engagement was shaped by sensory feedback, usability, and the need for support in interpreting health data. The technology offered both opportunities for connection and barriers to meaningful use.

Disrupted Natural Flow

Participants' experiences with WRF revealed a tension between guided synchronization and their authentic rhythm. To synchronize their heart rate and step rate, there was a disruption to their PA flow. Participants became conscious about how they move, and their exercise session became a deliberate practice. For participants, the device's requirements created a confrontation with their bodily rhythms. As P8 (female, 71 years) reflected, the expectation to "*go with your heart*" triggered a realization about her relationship with her body:

> *I have realised that I have never followed my heart. I walk much faster.* [P8, female, 71 years]

This shows how the synchronization challenge exposed participants' disconnection from their internal rhythms.

Moreover, a sense of inauthenticity and bodily disharmony prevailed when they attempted synchronization. Participants described feeling caught between complex demands, including their original moving patterns, environmental constraints, and the device's rhythmic imperatives. All the demands combined led to a cognitive burden for participants, which requires

XSL•FO
RenderX

constant attention and internal negotiation. Participants experienced this burden as fragmenting their usual unrestricted movement. As P18 (female, 67 years) described, "*even momentary lapses in attention resulted in failing synchronisation*," revealing how the device demanded a sustained cognitive effort with bodily rhythm that felt foreign to them.

Participants also experienced synchronization widely across different movement contexts. Flat terrain emerged as providing the most conducive environment, while stairs and uneven surfaces created barriers to synchronization. This suggests that the experience of rhythmic alignment is deeply contextual, shaped by the interplay between bodily capacity, environmental demands, and technological requirements. Environmental factors thus intensified their cognitive burden. Icy conditions, uneven terrain, and slopes created more layers of complexity that further estranged participants from feeling natural. P13's (female, 78 years) experience of "*when walking downhill, I need to slow down my steps to remain in sync*" illustrates how environmental contexts compounded the sense of imposition.

Learning and Guided Transformation

Despite cognitive struggles, some participants experienced a meaningful transformation in their relationship with synchronization. Their learning experience emerged as a gradual integration of guided rhythm in PA. P3 (female, 70 years) described the experience "*becoming like a dance*" once synchronized, suggesting a qualitative shift from effortful practice to embodied harmony. This transformation necessitated a reorientation in how participants perceived their bodies and movement. The warming-up process described by P3 also suggests that synchronization required not just physical preparation, but also an attentional preparation that allowed for the integration of heart rhythm awareness into movement consciousness.

The desire expressed by some participants (P12 and P14) to extend synchronization to other activities not included in the connected app, such as gym workouts or group settings, indicates an emerging appreciation for the device's potential in various scenarios. However, they noted a lack of guidance for these contexts as problematic, and customized guidance according to each activity will be needed, highlighting how rhythmic experiences could be further explored.

Raising Bodily Awareness Through Real-Time Multisensory Feedback

For participants, audio feedback served more than a technical feature; it is a medium that cultivates and maintains embodied awareness. The sound guidance raises present-moment consciousness, drawing participants into a close connection with their rhythmic movements. P3 explained the bridge between technological instruction and bodily understanding:

> *I focused on the beat and the sound. And there it (the synchronization) was much better.* [P3, female, 70 years]

This audio-mediated awareness helps to orient the walking experience into a contemplative practice. The synchronization between sound, step, and heart rate interweaves into a dynamic movement, where participants learned to listen and resonate not just with their ears but with their entire moving body.

Notably, this dynamic movement was fragile, easily disrupted by environmental distractions or cognitive overload, as mentioned in the Disrupted Natural Flow section, revealing how audio-guided synchronization demanded sustained and focused presence. To help with audio-guided synchronization, the integration of visual feedback created a richer source of engagement and accomplishment. Visual cues, including the changing numbers and colors, functioned as an immediate representation of participants' efforts, making abstract concepts of "being in sync" intuitively observable. With the interactive app interfaces and sounds, the compound feedback system gains a more meaningful and motivating guiding quality.

The device's capacity to provide a real-time compound feedback functioned as an extension of participants' bodily awareness during exercise. P13's experience demonstrated how RTF could recalibrate habitual movement patterns: "*Otherwise, I would walk too fast all the time*." This suggests that the device helps develop enhanced self-awareness, helping participants recognize and modify unconscious movement tendencies. For P1, the discovery of elevated heart rate during brief exercise periods created a sudden awareness of her body's responses that had previously remained hidden. This demonstrates how technological feedback could generate moments of surprise, revealing aspects that might otherwise remain unconscious. The real-time nature of the feedback opened up opportunities for immediate embodied learning, where wearers integrated technological information into the lived experience.

Wearables With RTF: Interpretation of Data

Overview

Participants' relationships with health data revealed intricacy between curiosity, confusion, and desire for meaning-making. The pulse data held significance as a direct representation of their most intimate bodily rhythm by making their heartbeat visible and quantifiable. This transformation of internal and felt experience into external and observable data created both fascination and interpretive challenges.

Relational Meaning-Making of Health Data

The participants struggle to understand how the data represent their health. Participants thus expressed a need for consultation and interpretation of data. P18's reflection captured this essential need:

> *It's fun (to get the data). But with the data, I would like to have a discussion (with others or professionals), so I can also understand the data.* [P18, female, 67 years]

This desire revealed that health data was not merely informational but deeply relational for these participants. The meaning of their physiological information emerged not in isolation but through conversation, interpretation, and contextualization within their broader life experiences.

XSL•FO
RenderX

The absence of data interpretation left participants with pieces of embodied information that lacked coherent meaning or actionable significance. P6's confusion, "*I do not understand why I get this information*," also highlighted how health data without interpretive support could create disorientation rather than empowerment. This suggests that meaningful engagement with data requires not just data provision but spaces for sense-making, where technological information becomes integrated into participants' knowledge of their own well-being.

Technological Barriers Hindering PA Enhancement

Participants' encounters with technical challenges revealed how technological complexity could fracture the intended engagement. P7's struggle with volume settings exemplified how technical barriers could create frustration. Also, P11's frustration revealed how technological barriers could create alienation from one's own embodied data, transforming what should be empowering information into a source of confusion and inadequacy.

> *I could not find information, like my heart rate, since I didn't know where to look for it.* [P11, female, 70 years]

These moments of technological breakdown highlighted the fragility of the wearer-device relationship and the importance of seamless integration for meaningful embodied engagement, so that the technological exclusion will not alienate the participants from the device's capabilities due to the technical limitations. This tension highlights the mismatch between technological promise for enhanced bodily awareness and the reality of technical complexity for wearable devices.

Wearables With RTF: Temporal Trajectories of Device Engagement

Overview

During the 3-week study period, the 17 participants (P1-P18, excluding P8) showed highly variable engagement with the device. While the recommended usage was 30 minutes per session, 3 times weekly (270 minutes total), actual usage time ranged from 51% to over 700% among the participants. P2 used the device least (137 minutes, 51% of recommended), while P9 showed the highest engagement (1905 minutes, 706% of recommended). On average, participants used the device for 720 minutes, nearly 3 times the recommended amount (267%).

We grouped participants into 3 categories based on total usage time—limited engagement (≤150% of recommendation) included 6 participants (P2, P3, P5, P11, P13, and P14), moderate engagement 150%-300% of recommendation) comprised the majority with 7 participants (P1, P4, P10, P12, P15, P16, and P18), and high engagement (≥300% of recommendation) included 4 participants (P6, P7, P9, and P17). The threshold of 150% and 300% was chosen based on the empirical distribution of the data and interpretability considerations. When we examined the actual usage patterns, they emerged as a natural break point that meaningfully separated participants with different engagement levels with the device.

Session patterns also varied considerably, with some participants preferring fewer but longer sessions (eg, P4 and P9 averaged over 60 minutes per session) while others engaged more frequently with shorter durations (eg, P15 and P16). Detailed engagement data and participant groupings are provided in Multimedia Appendix 5.

The 3 groups of device usage time became a lens through which different dimensions of the lived experience unfolded. Wearer-device relationships evolved with usage time. Limited engagement often brought frustration, moderate use led to reflection, and extended engagement fostered mastery and integration. Over time, some users shifted from resistance to routine, showing how long-term interaction could transform technology from a burden into a meaningful part of PA.

Disruption and Emerging Connection in Limited Engagement

For participants who engaged themselves for shorter durations (≤148% of the recommended 270 minutes, ie, ≤400 minutes), the experience was characterized by a critical awareness of bodily disruption and cognitive demand. P11 (97%) described her encounter with the device as requiring her to alter her way of exercising:

> *I am a fast walker, so walking too fast got uncomfortable (to synchronize with my heart rate). It required too much effort and focus to follow the exact goals.* [P11, female, 70 years]

This disruption of habitual movement patterns created a tension between her natural bodily rhythm and the technologically mediated pace. P13 (112%) experienced a similar disruption of her natural walking cadence, describing the necessity to walk more slowly as counterintuitive:

> *My heartbeat often was between 70 and 80, and that is really slow to walk. But it was hard to walk that slowly... You have got to go really slowly to be in time, in sync.* [P13, female, 78 years]

Despite this challenge, she found meaning in the device's auditory feedback, which became a source of guidance and positive effect:

> *It is helpful when (the sounds) tell you when you are not in sync... There is a happy telephone sound when you are in sync.* [P13, female, 78 years]

P3 (132%), despite her limited usage time, experienced a profound transformation in her relationship with the device over time. Her lived experience evolved from initial struggle to proficiency:

> *The first week, I was 69% synced. The following week, I achieved 95% sync, and in the last week, I reached 97% sync.* [P3, female, 70 years]

This progression revealed how even limited temporal engagement could yield significant shifts in competence and connection with the technology.

Awareness and Growth in Moderate Engagement

Among participants who used the device between 148% and 333% of the recommended dosage (approximately 400-900

XSL•FO
RenderX

minutes), no particular positive or negative feelings were articulated toward the device. In this group, participants expressed a neutral observational attitude toward their synchronization performance. Interestingly, their awareness of the synchronization fluctuations during each session sometimes raises curiosity for them to reflect on their embodied experience. For example, P18 (156%) was fascinated by the dynamic, ever-changing nature of synchronization:

> *That is interesting to see how it fluctuates all the time... it really went, from like 61 (to) 68 and then it was 64 and then it went up to 78 and it was really up and down.* [P18, female, 67 years]

This temporal awareness revealed how moderate engagement fostered a contemplative viewpoint toward her own bodily processes.

Throughout the entire study period, P12 (272%) also experienced a changing synchronization rate, marking a journey of progression. His extended engagement with the device brought joy in improvement and a sense of achievement for him:

> *In the beginning, this was a hard day. Only 21%... but now this is 90%! Perfect.* [P12, male, 72 years]

Extended usage thus for P12 became a narrative of personal growth and technological competence.

From Discipline to Integration in Extended Engagement

All participants who engaged with the device for extended periods (≥333% of the recommended dosage, ie, over 900 minutes approximately) developed strategies and demonstrated discipline when interacting with it, creating a nearly self-training process.

P16 (348%) expresses that she put in intense focus, which demanded a withdrawal from environmental engagement:

> *You must be so focused, extremely focused. If you see a nice sky or some flowers, you are not in focus again... You need to always concentrate on this device instead of this environment.* [P16, female, 66 years]

Her experience revealed the demanding nature of long-term synchronization, requiring a narrowing of perceptual attention.

P7 (567%) experienced the longest engagement with the device and developed a profoundly different relationship with the technology. For him, extended usage transformed the device from a demanding technological interface into a meditative companion:

> *In the end, I found that sound pleasant. It calmed me down... It reminds me of meditation... I did not have to think about anything.* [P7, male, 76 years]

His extended temporal engagement allowed for the emergence of a peaceful relationship with a familiar, internalized synchronization process.

Discussion

Principal Findings

In this study, we have explored the lived experiences of physically active older adults in using wearables for rhythmic activity, with a specific attention to RTF as an interaction modality. The study explored older adults' previous use of wearables to track their PA, adherence with WRF during rhythmic activity, and the interactive features of WRF in enhancing the synchronization between step rate and heart rate. The study identified four main themes characterizing older adults' lived experiences with wearables that are (1) use of wearable technologies without RTF in daily life, (2) embodied rhythmic negotiation with RTF, (3) interpretation of health data with RTF, and (4) temporal trajectories of device engagement with RTF.

While previous studies on wearables with older adults have recognized diverse motivations for adoption [11,12,33-35], this study reveals the specific mechanisms underlying this diversity in the context of real-time rhythmic guidance. Rather than treating heterogeneity as a static characteristic, we demonstrate how varied engagement patterns emerge through the dynamic intersection of personal values, embodied experiences, and technological demands. This study's contribution extends beyond documenting diversity to explaining how older adults' relationships with wearable technology are fundamentally shaped by their commitment to preserving authentic bodily experiences, their reliance on social networks for technology validation, and their need for contextually adaptive feedback systems that respect individual rhythmic patterns.

The study shows that the discontinuous use of wearables, accompanied by self-reported challenges in the device-guided synchronization, can be partly explained by the mismatch between technological capabilities and older adults' inherent values and aspirations in later life. Factors such as comparison, competition, and goal setting that are often inherently built into commercial wearables [62] are less important for this demographic, for whom it is often more important to maintain the existing PA level through inner self-motivation. Simultaneously, device-guided synchronization requires older adults to change their natural walking rhythm and pace, which may result in a sense of discomfort and frustration. These age-specific requirements for achieving device-guided synchronization have largely remained unexplored in previous studies [30,58]. To overcome these challenges, the study proposes that interaction modalities that guide users to increase their bodily awareness may help older adults to find the right walking pace authentically.

The study addresses that older adults' desire to use wearable devices stems mostly from their health-related goals and preferences, rather than their need for constant digital monitoring. These personal goals and preferences may show high variance in later life, which can partly explain the heterogeneity in driving factors to use wearables. Importantly, the findings reveal more than simple disuse but an intentional distancing from technology. This distancing aligns with research showing that older adults may abandon wearables when they

XSL•FO
RenderX

are framed as assistive technologies that compensate for age-related losses, leading to negative user images [36]. Moreover, wearables can be perceived as motivating or condescending depending on how freely older adults are able to make autonomous choices about PA [34]. As a result, technology adoption among older adults involves complex value-based decision-making processes that prioritize the preservation of unmediated bodily experience over external validation.

Individuals' readiness to accept wearable technology varies depending on their interests, experiences, and sociocultural background [32,63]. This study indicates that personal goals, often focused on the enjoyment of PA, were stated as the primary motivator to use wearables. These personal goals may sometimes contradict the device-related features that emphasize self-monitoring or goal setting in PA [34], which may partly explain the low or limited use of wearables in PA among older adults.

Previous research has explored the use of wearables by focusing on older adults' motivations and driving factors at the individual level or from the device-centric perspective [11,33,35]. The study adds to this line of research by demonstrating the social aspects and motivations in the use of wearables for PA. The results demonstrate that technology adoption emerged not as an individual consumer choice, but as a socially embedded practice mediated through relationships, community connections, and shared experiences. This relational orientation, evidenced through participants' learning via community seminars, family introductions, and the emotional significance attached to devices, challenges dominant narratives that frame wearable technology use as primarily self-directed and autonomous. This finding supports previous research indicating that formal and informal support and guidance in accessing and continuing device use are connected to long-term adoption [37]. The relational dimension extends beyond initial adoption to ongoing meaning-making, where device data interpretation requires dialogical engagement with professionals or trusted others. The combination of individual motivation, ease-of-use, and perception of added value ultimately determines whether devices will be integrated into users' lives [11,33]. This shows that the role of family members or friends, also known as "warm experts" [17], remains significant in the uptake of wearables. Consequently, social support in the uptake of wearables, which is often unequally distributed in later life [64], could further diversify the heterogeneous use of wearables in PA.

The negative narratives we observed serve as a vital reminder that technology and health data can alter participants' relationships with their bodies, shifting their view from an intuitive and instinctive feeling to one of external judgment and evaluation. The fact that decreased activity levels led to stress, rather than simply providing information or motivation, suggests that when technology introduces an evaluative aspect to PA, it might be emotionally challenging if not carefully designed. This emotional dimension is critical, as research demonstrates that long-term attachment with wearables requires devices to elicit positive emotional responses among users [40], and that emotional, sensory, and social influences significantly impact user engagement with wearables [13,38,39]. A long-term, motivating engagement with wearables also requires participants to develop strategies for managing the emotional impact, involving selective engagement and conscious boundary-setting around metrics. Fostering personalized approaches that preserve their sense of agency will be the key to selectively engaging with technologies that align with their values and needs.

Lived Experiences of Wearables With RTF

The study reveals the significant age-related variations in user experience and adaptation to the wearable with RTF. Central to these findings is the recognition that rhythmic synchronization is deeply contextual, shaped by the interplay between bodily capacity, environmental demands, and technological requirements. The results demonstrate how synchronization challenges were not uniform technical difficulties but varied significantly based on environmental factors (flat terrain vs stairs and uneven surfaces), individual bodily characteristics (natural walking pace and heart rate variability), and temporal factors (time needed for adaptation). This aligns with research showing that through sound interaction, users can coordinate and stabilize movements with internal or external imposed rhythms [28], and that auditory feedback allows users to be observant of the environment and fits into more dynamic settings compared with visual and tactile guidance [27]. This contextual nature means that synchronization cannot be understood as a purely technical challenge, but rather as a complex negotiation between multiple intersecting factors that are dynamically configured in each exercising session.

Regarding synchronization challenges, older adults encountered difficulties synchronizing their steps to the audio feedback designed to align with their heartbeats. These challenges stemmed from a mismatch between the device's requirements and the cognitive load, as well as from environmental constraints. Participants reported that synchronizing often required them to walk at an unnaturally slow pace, which conflicted with their habitual walking styles. This resulted in a perception that the device's requirements were intrusive and disruptive to the natural flow of walking. Despite these challenges, older adults demonstrated an ability to improve their synchronization over time. This improvement, however, was not uniform across participants and appeared to depend on the individual's personal exercise routines.

The study indicates that device-guided synchronization in rhythmic activity can be associated with older adults' previous routines and rhythms, and thus connected to temporalities of PA. These insights suggest that while initial engagement with the device may be frustrating, persistence and strategic adjustments could enhance the experience of synchronization for some users. These adjustments, however, require "bodily knowledge and know-how" [65] to be able to adapt the device to already existing exercise routines. As Phoenix and Bell [66] highlight, disruptions in the natural movement rhythms may be associated with bodily discomfort and emotions, including symptoms associated with chronic health conditions connected to aging. These findings highlight that the device-guided synchronization, despite being a physiological mechanism between heart and gait cycles [30,58], is always connected to wider routines, rhythms, and temporalities in PA, as well as

XSL•FO
RenderX

older adults' previous exercise background and physical capabilities. In this study, the interconnectedness of synchronization challenges in relation to the environmental or activity-related factors was repeatedly pronounced in participants' statements. This interconnectedness between synchronization and contextual and environmental factors may explain the reason for participants' frequent statements of synchronization challenges, despite the fact that the device itself was considered relatively easy to use.

Overall, the device created both disruption and possibility, disrupting established movement patterns while opening space for new forms of bodily awareness and rhythmic experience. The challenge of synchronization revealed the depth of participants' disconnection from their internal rhythms and their capacity for developing integration when given appropriate support and practice. This dual nature is inherent to RTF mechanisms, which provide haptic, auditory, or visual feedback simultaneously with user movement rather than after the activity has ended [2,3]. Notably, RTF has been identified as a preferred feature among older adults in wearable technologies [11]. In this sense, wearable devices with RTF function not merely as monitoring tools, but as mediators that can either fragment or enhance the relationship between consciousness and embodied movement, depending on how they are designed and implemented.

Meaning-Making of Multisensory RTF

The meanings associated with the interactive features of WRFs extended beyond functional utility. The study addresses the potential of real-time audio feedback to help older adults overcome synchronization challenges and adapt to device-related functionalities over time.

First, RTF in auditory format can help older adults to reduce cognitive load in synchronization, which was considered to require an intense focus on finding and maintaining the right walking pace. Previous studies, respectively, have explored the auditory feedback in relation to increasing the enjoyment in walking activity, and showed that auditory cues could enhance the health benefit from walking among older adults through acting as a positive reinforcement to a rhythmic stepping pattern [67]. However, the degree of adherence to these feedback modalities depends strongly on individual characteristics, such as technological familiarity, cognitive capacity, and even sensory limitations. According to this study, older adults with more previous experience with technology tend to engage more easily with both visual and auditory feedback.

Second, the study shows that compound feedback, which combines visual and aural cues, improves synchronization and has a positive impact on the overall experience. Although its effectiveness may vary depending on individual needs and preferences, this strategy is especially helpful in fostering positive emotions like motivation and enjoyment. In order to accommodate a greater range of sensory abilities and preferences, wearable device design must be adaptive to an individual's skills and capabilities. For example, older adults with hearing impairments may find auditory feedback less effective, while those with visual impairments may prefer larger visual cues.

Finally, temporal engagement with the device was not merely quantitative but fundamentally shaped the qualitative nature of participants' lived experiences. Shorter engagements were characterized by disruption and effortful adaptation, while extended engagements allowed for the development of more integrated, contemplative, or mastery-oriented relationships with the technology. The duration of usage emerged as a critical factor in determining whether participants experienced the device as a disruptive intervention or as an integrated tool for embodied self-awareness, and potentially a natural component in PA. This temporal dimension is particularly significant given that adherence, defined as long-term user acceptance and engagement with devices, remains a persistent challenge in wearable technology research [4-6]. The individual factors of motivation, ease-of-use, and perceived added value that determine device integration into users' lives [11,33] appear to require extended time periods for meaningful development. To sum up, technology adoption among older adults requires sufficient time for the development of new embodied competencies and the gradual integration of technological feedback into existing movement practices. The transformation from initial resistance or struggle to potential acceptance suggests that wearable technology design should accommodate extended adaptation periods rather than expecting immediate integration.

Limitations and Future Research

The study gathered older adults with relatively high levels of PA and high satisfaction with their physical health. Therefore, their user experience with the device could potentially be influenced by their previous PA level. The participants used the device only for a 3-week period, and the long-term user engagement remained unexplored. Despite these limitations, this study has extended previous research by considering the lived experiences of older adults in device-guided rhythmic activity, with a specific focus on audio feedback during synchronization of step and heart rate. Future research should explore device-guided synchronization and adherence to RTF with a more diverse group of older adults. This would ensure that wearable technologies for self-monitoring can reach their expected health benefits for those older adults who are at risk of cardiovascular disease.

Conclusions

This study reveals that older adults' engagement with wearable devices for rhythmic activity is characterized by 4 fundamental dimensions that challenge conventional assumptions about technology adoption in later life. First, rather than simple disuse, older adults demonstrate intentional distancing from wearable technologies, actively resisting digital mediation to preserve authentic relationships with PA. Second, their engagement is fundamentally relational rather than individualistic, emerging through trusted social networks and requiring ongoing dialogical support for meaningful data interpretation. Third, the experience of rhythmic alignment is deeply contextual, shaped by dynamic negotiations between bodily capacity, environmental demands, and technological requirements that vary significantly across individuals and situations. Fourth, temporal trajectories of engagement reveal that meaningful relationships with wearable

XSL•FO
RenderX

technology develop through extended interaction periods, with different engagement durations producing qualitatively distinct experiences ranging from disruption to integration.

These findings extend previous research on wearable technology use among older adults by moving beyond motivational factors to reveal the underlying experiential mechanisms that shape engagement patterns. The study demonstrates that device-guided synchronization creates both disruption and possibility, requiring extended temporal engagement for participants to develop integrated relationships with technological feedback. While RTF shows potential for enhancing bodily awareness, its effectiveness depends on designs that accommodate older adults' commitment to embodied autonomy, their relational approach to technology validation, and the contextual nature of their rhythmic experiences. Future wearable technologies must therefore prioritize adaptive, socially embedded, and temporally sensitive design approaches that respect rather than override older adults' established movement practices and values.

Abstract

Background: Over the past 2 decades, global rates of cannabis use have risen significantly, especially among young adults. This has corresponded to an increase in cannabis-related problems and hospitalizations. Thus, there has been significant interest in developing new interventions that can help facilitate cannabis cessation and reduce hospitalization rates. Specifically, mobile apps have emerged as scalable and accessible stand-alone or adjunct interventions that can help individuals with cannabis use disorders.

Objective: This study aimed to evaluate the quality of free cannabis cessation apps available on both the Apple App Store and Google Play Store, focusing on the analysis of their features, content, and adherence to evidence-based practices.

Methods: A systematic search was conducted in April 2023 using a variety of keywords. The apps were deemed eligible if they were free, available in English, accessible on both the Apple App Store and the Google Play Store, and related to cannabis cessation. Eligible apps were used for at least 1 month and were rated on the Mobile App Rating Scale by 2 reviewers. Interrater reliability was excellent, with a weighted Cohen κ of 0.893 (95% CI 0.835-0.943).

Results: Four apps were included in the analysis, namely, “Grounded–Quit Weed,” “Quit Weed,” “Marijuana Addiction Calendar,” and “Marijuana Anonymous.” The mean overall quality score of the apps was 3.4 out of 5, indicating poor to acceptable quality. The apps scored the highest on the “functionality” section and the lowest on the “information” section. Of the 4 apps, 3 focused on tracking cannabis use and duration of abstinence, whereas 1 focused on peer support. A limited number of cannabis cessation apps were identified, and those that were available were of low quality due to a lack of evidence-based information.

Conclusions: This study is the first to evaluate the current availability and quality of mobile apps designed for cannabis cessation. Unlike previous research that broadly assessed cannabis-related mobile apps, this study focuses on the limited number of free cannabis cessation tools, reflecting what is most available to the general population. The findings highlight a significant gap between the growing demand for virtual cessation tools and the quality of existing options. With the rising global prevalence of cannabis use disorders, there is an increasing need for robust, accessible, and evidence-based therapeutic options. While mobile health apps may be a viable option to support cannabis cessation, the current landscape is limited by poor quality apps and a lack of evidence-based information. From a real-world perspective, this study highlights the need for users to exercise caution when relying on current cannabis cessation apps and underscores the urgent need for the development and evaluation of new evidence-based digital interventions.

Introduction

On October 17, 2018, Canada legalized recreational cannabis through the Cannabis Act, making it the second country in the world, after Uruguay, to do so at the national level [1]. The act was initially passed to protect public health and safety by restricting youth access to cannabis, preventing inducement to use, reducing illicit production, providing access to a quality-controlled supply of cannabis, and enhancing public awareness of the health risks of cannabis use [2]. However, the legislation appears to have led to a marked increase in cannabis use across Canada [3,4]. In fact, in 2017, the Canadian Tobacco, Alcohol and Drugs Survey reported that the prevalence of past-year cannabis use was 15% [5]. This contrasts sharply with findings from the updated Canadian Substance Use Survey, which reported that 32.4% of the population used cannabis in the past 12 months in 2023 [6]. Furthermore, the 2021 Canadian Cannabis Survey indicated that 17% of Canadians aged 16 years and older reported using cannabis in the past 30 days, with an average consumption of 14.3 days [4]. Another study on cannabis legalization from 2001 to 2019 revealed significant increases in daily cannabis use, past 12-month use, and cannabis-related problems, with the prevalence of cannabis-related problems in Canada rising from 6% to 14% between 2004 and 2019 [7]. In 2019, there were 23.80 million cases of cannabis use disorder globally, with the age-adjusted highest number of incidences observed in high-income North America (121/100,000) [8].

A study combining 19 iterations of the Centre for Addiction and Mental Health Monitor Surveys using a pre-post design found that young adults (aged 18-34 years) had higher rates of cannabis-related problems, such as dependence, anxiety, depressive disorders, and physical health effects, than their older counterparts [7,9]. Although younger individuals continue to exhibit higher levels of cannabis use, the largest rise in consumption since legalization was observed among middle-aged and older adults (those aged 45-64 years and ≥65 years, respectively) [7]. It was concluded that the Cannabis Act was strongly associated with an increased likelihood of cannabis use, daily cannabis use, and cannabis-related problems, including dependence [7]. This finding is supported by Ontario Cannabis Store reports stating that total cannabis sales in Ontario increased by 182% (from 35 million grams to 99 million grams) between the first and second fiscal years [10,11].

According to the Canadian Institute for Health Information, cannabis was the leading contributor to hospitalization rates for substance use among youth aged 10 to 24 years (40%) between 2017 and 2018 [12]. For those aged 25 and older, cannabis was associated with 11% of hospitalizations [12]. Given the age-standardized rate of 104 per 100,000 for youth hospital stays caused by cannabis harm, it is clear that significant resources are required to address youth-specific substance use needs, including timely access to prevention, intervention, and treatment services [12]. Nonetheless, addiction treatment wait times have increased over the last decade, with the average wait time for residential programs reaching 50 days by 2019. Many clients were reported to have been hospitalized, incarcerated, to have attempted suicide, or to have died while awaiting treatment [13].

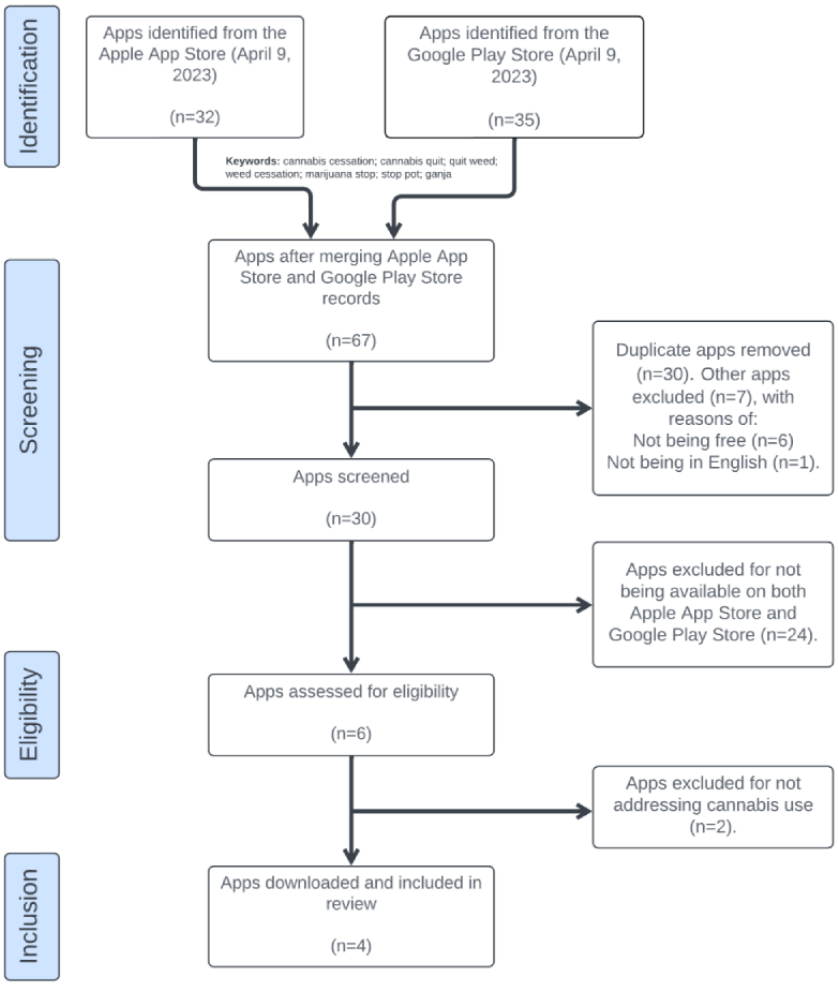
Various methods can be used to facilitate cannabis addiction treatment, such as cognitive behavioral therapy, which aids individuals in identifying and correcting problematic behaviors, including addiction [14]. Contingency management is another approach that monitors target behaviors and provides or removes tangible rewards to reinforce positive behaviors [14]. Although no medications are currently approved for cannabis use disorder therapy, some are being trialed to help control withdrawal symptoms, and newer clinical trials are focusing on allosteric modulators to inhibit cannabis's rewarding effect [15].

Mobile phones have revolutionized communication technology, enabling users to access various apps for different purposes. As of 2021, this technology reached a global audience of 6.4 billion individuals and continues to grow, making it pervasive and widely used [16]. Current literature has documented the use of mobile apps for alcohol and tobacco dependence, and research suggests that these apps may promote successful quit attempts among e-cigarette users or vapers [17-19]. The available apps focus on habit tracking, therapy, or education as their primary mode of effectiveness. However, there has been limited research into mobile apps that can be used to facilitate cannabis cessation. This is a pressing issue, as cannabis use is rising globally [20]. In 2014, a content analysis of apps about cannabis on the Apple App Store and the Google Play Store was conducted; however, despite their extensive searching, they only found 1 app that was aimed at promoting cannabis cessation [21]. Since then, the mobile health (mHealth) field has grown significantly, and thousands of new apps have been added to the Apple App Store and the Google Play Store. With the growing field of mHealth, the increasing prevalence of mobile phone use, and the role of technology in disseminating cannabis-related news and information, this study aimed to examine the quality of cannabis cessation apps available in the marketplace, their content and features, popularity among users, and adherence to evidence-based practices. This study primarily focused on free English-language mobile apps available in both the Apple App Store and the Google Play Store.

Methods

Search Strategy

Using the search terms "cannabis cessation," "cannabis quit," "quit weed," "marijuana stop," "stop pot," "weed cessation," and "ganja," the primary and secondary authors searched the Canadian Apple App Store and Google Play Store in April 2023 for smartphone apps targeting cannabis cessation. Searches were conducted directly within the embedded mobile app store platforms rather than their corresponding websites to ensure that the results reflected how users typically discover and download apps.



XSL•FO
RenderX

Eligibility Criteria

Mobile apps related to cannabis cessation or cannabis behavior modification were included. Apps that were not available for free download or were not in English were excluded. Only free apps were included as they tend to have higher use and accessibility for the general population than paid apps. Apps that were not available on both the Google Play Store and the Apple App Store were also excluded. The Google Play Store and the Apple App Store were selected as the 2 markets of interest, as these platforms are responsible for the largest market share of users [22].

Once ineligible apps were removed through a preliminary screening, the remaining apps were examined by checking their descriptions, profiles, relevance to cannabis cessation, and functionality. Those that did not meet the required criteria were excluded. The remaining eligible apps were then independently reviewed by the primary and secondary authors through a 2-pronged screening approach. First, the profiles of the apps were examined on the online app stores, and second, an ancestry search of developer websites, profiles, and overall online presence was conducted when information was available. Apps that were confirmed to have no association with cannabis cessation were excluded, resulting in a final sample of 4 apps. A detailed summary of the inclusion and exclusion process can be seen in Figure 1.

Figure 1. Flow diagram showing the identification, screening, eligibility assessment, and inclusion of cannabis cessation mobile apps for further Mobile App Rating Scale analysis.

Assessment of Quality, Contents and Features, and Popularity Among Users

To ensure the accuracy and reliability of our results, each app was rigorously tested over a short period (up to 1 month). This allowed us to classify the apps based on quality, features, and content and to perform the necessary evaluation of these tools. A variety of metrics, including the number of downloads, the number of reviews, and the overall user ratings, were also collected when available. We exclusively assessed the apps on Apple devices. This was because the Apple ecosystem provides a more consistent experience across devices, minimizing the variability associated with different hardware and software configurations found in Android devices.

The quality of each app was evaluated using the Mobile App Rating Scale (MARS), which is a multidimensional measure that is designed to rate the quality of mHealth apps [23]. The MARS has been specifically designed to evaluate mHealth apps and has been validated as a reliable measure of health app quality [23]. The scale comprises 5 categories—engagement,

XSL•FO
RenderX

functionality, esthetics, information quality, and subjective quality—with a total of 23 collective items rated using a 5-point scale. For items that could not be adequately assessed, an option of "not applicable" was available. The MARS also includes a subjective quality category; however, it was not factored into the final score.

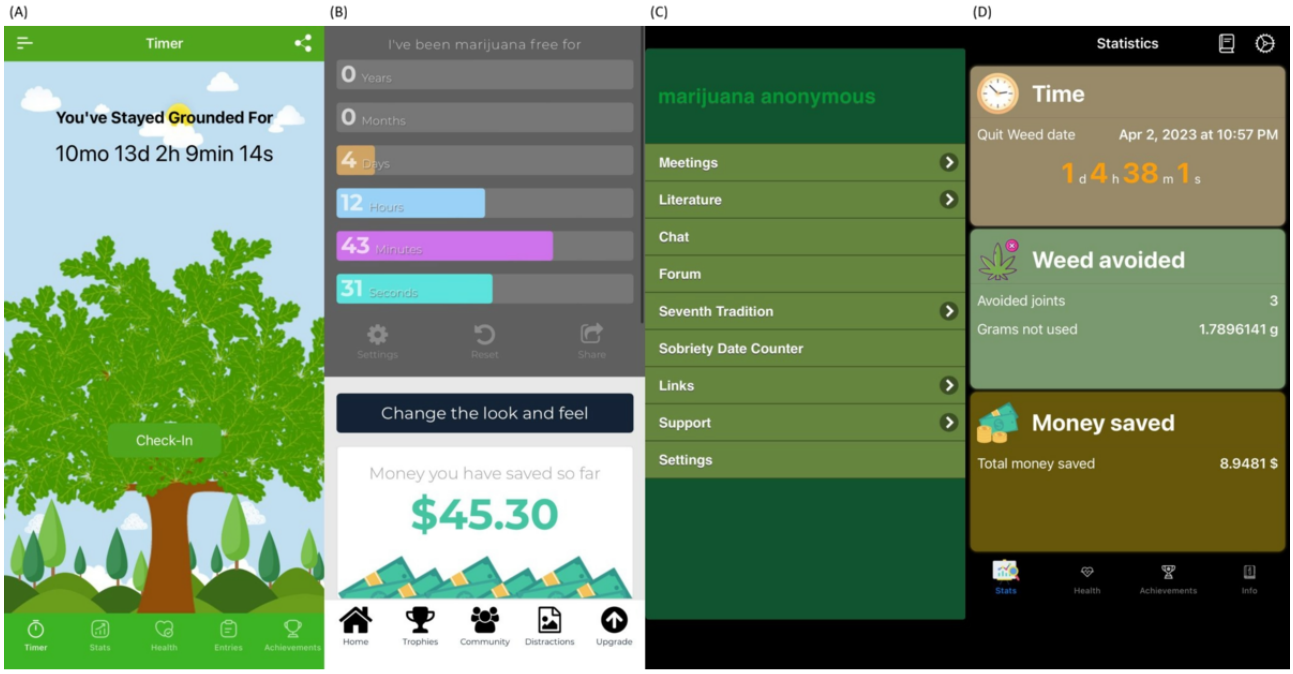
To identify the strengths and weaknesses of each app, mean scores were calculated for each of the 4 objective categories, while the sum of all 4 category scores provided an overall quality score for each app. However, given the variability among health-related apps, the MARS does not provide a defined threshold for the type of scores a high-quality app should obtain on the scale. The use of the MARS and the overall methodology were based on a previous study that assessed the quality and content of mobile vaping cessation apps [19]. A MARS total mean score of 3.0 was established as the cutoff for apps with acceptable quality [19].

Data Extraction and Quality Assessment

Two raters tested the MARS with a randomly selected app. Results from the test app showed substantial agreement, with minor differences (≤2 points) that were discussed and resolved. The remaining apps were then independently evaluated and once again showed excellent agreement between the 2 reviewers (≤2 points). The weighted Cohen κ score was 0.893 (95% CI 0.835-0.943).

Ethical Considerations

This paper does not include any studies involving human participants or animals conducted by the authors; therefore, informed consent was not required. Institutional review board approval, privacy, or compensation statements do not apply to this study. All information is publicly available.



Results

Overview

Following a comprehensive screening process, 4 cannabis cessation mobile apps were identified. The full app selection and screening process can be seen in Figure 1.

On the basis of the inclusion criteria, we selected the following four apps: (1) "Grounded–Quit Weed," (2) "Quit Weed," (3) "Marijuana Addiction Calendar," and (4) "Marijuana Anonymous." Figure 2 provides a visual overview of the 4 apps included in the analysis.

Figure 2. Visual overview of the 4 mobile apps included in the analysis. (A) Grounded–Quit Weed, (B) Marijuana Addiction Calendar, (C) Marijuana Anonymous, and (D) Quit Weed.

General Assessment of Mobile Apps

The overall mean score for the MARS app quality was 3.4, indicating a poor to acceptable quality of the apps. Among the 4 apps, "Grounded–Quit Weed" and "Quit Weed" received the highest score (3.7 each), while "Marijuana Anonymous" received the lowest score (2.8).

On average, the functionality category received the highest mean score (4.3), followed by engagement (3.2), esthetics (3.2), and information (2.8). The full app score breakdown can be seen in Table 1.

RenderX

Table 1. Characteristics of mobile apps based on publicly available information from the Apple App Store and Google Play Store, along with average Mobile App Rating Scale (MARS) scores. The maximum possible average score is 5.

Characteristic	Grounded–Quit Weed	Marijuana Addiction Calendar	Marijuana Anonymous	Quit Weed
App classification	Tracker	Tracker	Support meetings	Tracker
User rating on Apple App Store	4.7	4.4	2.8	4.9
User rating on Google Play Store	4.4	3.1	4.1	4.6
Number of downloads on Google Play Store	>50,000	>10,000	>10,000	>50,000
Engagement	3.6	4.0	1.7	3.4
Functionality	4.3	4.0	4.0	5.0
Esthetics	4.3	2.7	2.3	3.3
Information quality	2.8	2.3	3.0	3.0
MARS total mean score	3.7	3.3	2.8	3.7

Grounded–Quit Weed

The “Grounded–Quit Weed” was one of the highest scoring apps based on the MARS analysis. It was also the most downloaded app on the Google Play Store. The app began by asking the user a series of questions regarding their cannabis use, specifically about the number of grams used per day, the price per gram, and the quit date. The app also asked users to specify their goal, whether it was quitting cannabis completely, taking a tolerance break, or simply tracking use. The app then used a timer to track the amount of time an individual spent abstaining from cannabis use. Additionally, the app reported the approximate money saved and the amount of cannabis avoided.

The app also featured a journaling component, which allowed users to “check in” by recording whether they used cannabis, the quantity they used, the total amount of money spent, the number and intensity of urges, the type of equipment used, and the date and time of each entry. This enabled users to monitor and analyze the frequency and intensity of their urges to help identify possible triggers. The feature for monitoring withdrawal symptoms and recording detailed trigger information was only available in the paid version of the app and thus was not evaluated. The app included a “Motivation” subsection, which provided users with daily rotating quotes. Additionally, the app included an achievements tracker and a visual representation of user progress, depicted by a tree that grew larger with continued abstinence.

The “Grounded–Quit Weed” app included a “Quit Guide” section that offered limited educational information on cannabis cessation. This section divided the quitting process into 3 distinct phases, providing brief descriptions of each phase, including common side effects, associated thoughts, and guidance on identifying the user’s current stage. However, the app did not provide citations or references to support this phase-based framework. Additionally, the app featured a “Library” section linking to the Grounded420 website, which covered topics such as “What is CBD?” and “What is CHS?” Of these, only the “What is CHS?” paper included citations. Further exploration of the website revealed a range of blog posts on cannabis cessation; however, many of these papers lacked references, which brings into question the credibility and evidence base of the content provided.

The app advertised a community chat feature; however, this was available only in its premium paid version and thus was not evaluated.

Quit Weed

The “Quit Weed” app used a similar approach to the “Grounded–Quit Weed” app by tracking the time users spent abstaining from cannabis use. Users could enter their average weed use, cost, and quit date in the settings. This app then tracked the approximate amount of cannabis avoided and the approximate money saved. This app also tracked the side effects users may experience during the quitting process and the duration required for those side effects to resolve. While there were references and citations in this section, many were not from peer-reviewed journal papers.

Similar to “Grounded–Quit Weed,” this app had an “Achievements” section, which gave badges based on the number of joints avoided, grams of cannabis avoided, and money saved. The app also seemed to have a motivation section; however, this feature was locked behind a paywall and thus was not evaluated. The app also seemed to have information on recovery phases and associated side effects; however, this content was also blocked behind a paywall and thus was not evaluated.

Marijuana Addiction Calendar

The “Marijuana Addiction Calendar” also used a timer to track the amount of time users spent abstaining from cannabis use. Similar to “Grounded–Quit Weed”, the app asked for information about the amount of money spent on marijuana per day, the amount of time spent smoking marijuana, the user’s quit date, and the reason for quitting. The app also calculated the money and time saved by not smoking.

The app also had a “Distractions” section, which contained a limited selection of images, sounds, games, and workouts. However, there were only 2 categories of images and 1 category of sounds that were available in the free version. The rest of the images, sounds, and games were restricted to the paid version and thus were not evaluated. The workout section was actually

XSL•FO
RenderX

an advertisement for another mobile app and was also not evaluated. Additionally, this app had a "Trophies" section associated with duration of abstinence, ranging from 1 week up to 15 years.

The app also had a community chat feature, which allowed users to post in the forum after signing in with their Apple account. The forum was not very active, with only a few users using this feature weekly. Discussions and posts typically centered on individuals' initial attempts at quitting; documenting their setbacks; and seeking advice, strategies, and encouragement. Users are also able to like, reply to, or flag other user's comments as inappropriate. However, users with free memberships were limited in how much they could post. The app also had a secondary feature that allowed users to submit testimonials about the effectiveness of this app on their quitting journey. These testimonials were then displayed to all users. The app also showed frequent full-page advertisements when switching between pages or tabs within the app.

Marijuana Anonymous

The "Marijuana Anonymous" app functioned primarily as a networking tool to locate licensed Marijuana Anonymous meetings nearby. Although it included a feature to track abstinence duration, this feature was minimal, allowing users to enter only a start date. The app did not provide any educational content on cannabis cessation but instead had a range of documents that described the purpose of "Marijuana Anonymous," the tenets of the organization, stories from individuals in the organization, and information about their 12-step abstinence process. It was noted that these documents and texts had heavy religious and biblical undertones. Although the primary intended function of the app was to help users locate active meetings, the location-based search feature was nonfunctional at the time of evaluation, limiting its utility. Consequently, the app displayed all scheduled meetings without filtering by user location.

A summary of app features and premium membership pricing can be seen in Table 2.

Table 2. App features available in each analyzed mobile app.

Feature	Grounded–Quit Weed	Quit Weed	Marijuana Addiction Calendar	Marijuana Anonymous
Time since cessation	✓	✓	✓	✓
Money saved	✓	✓	✓	—[a]
Time saved by avoiding smoking	—	—	✓	—
Cannabis avoided	✓	✓	—	—
Goal setting	✓	—	✓	—

Pricing for premium (CAD $1=US $0.75 as of July 2023)	CAD $7.49/month; CAD $35.99/year	CAD $13.99 (one-time payment)	CAD $6.49/month; CAD $52.99/year	—

[a]Not applicable.

[b]Premium content that has not been evaluated.

[c]Educational content is about the Marijuana Anonymous method of quitting rather than about cannabis cessation in general.

Discussion

Principal Findings

This is the first study that aimed to evaluate the effectiveness of mobile apps for cannabis cessation and assess the current mobile app market in this regard. The study identified 4 apps available on both the Apple App Store and the Google Play Store for cannabis cessation, namely, "Grounded–Quit Weed," "Quit Weed," "Marijuana Anonymous," and "Marijuana Addiction Calendar." The apps were evaluated using the MARS scale and received an average score of 3.4. The "Grounded–Quit Weed" and the "Marijuana Addiction Calendar" apps received the highest score, whereas "Marijuana Anonymous" received the lowest score. "Grounded–Quit Weed," "Quit Weed," and "Marijuana Addiction Calendar" were use tracking apps, whereas "Marijuana Anonymous" was primarily focused on connecting individuals with local Marijuana Anonymous meetings. The results of this study offer valuable insights into the state of the mobile app market for cannabis cessation. Specifically, these results showcase the relative undersaturation of the mobile app field for cannabis cessation. When compared to smoking or vaping cessation mobile apps, it was found that there were significantly fewer apps for cannabis cessation [18,19].

XSL•FO
RenderX

The apps evaluated in this study had significant variability in their comprehensiveness, accessibility, evidence base, and overall quality. While "Grounded–Quit Weed" offered the most extensive range of features, it, like the other apps, lacked appropriate citations and references to support its educational content, limiting the credibility of the information provided. This pattern was reflected in the MARS analysis, in which the apps scored the lowest in the "information" category, suggesting a lack of evidence-based content within the apps. This is likely because clinicians were not involved in the development of these apps, and instead, the apps were focused on creating an engaging and functional experience rather than one that was empirically grounded. This is a critical gap in the field, as recent research has shown that evidence-based mobile apps for behavioral modification, both as stand-alone tools and as part of an intervention, have advantages over standard health interventions [24]. Despite the overall positive correlation between mobile apps and behavioral modifications in the literature, the heterogeneity of results suggests that more research is needed to determine the specific types of mobile apps and features that may yield the most significant benefits for users seeking cannabis cessation support [24].

Use tracking was the most commonly used strategy among both the analyzed and excluded apps. Most apps primarily focused on tracking the duration of cannabis cessation and reporting auxiliary information such as money saved. Although some other features were identified, such as the in-person community meetings associated with the "Marijuana Anonymous" app, a greater variety of strategies and tools is needed within the existing set of apps. Recent research has demonstrated the high efficacy of personalized medical apps, such as artificial intelligence chatbots that adapt to users, in changing health behaviors [25]. The apps should be designed to adapt to users' moods, preferences, and patterns of use to provide personalized health care support and maximize effectiveness [25]. However, more extensive randomized controlled trials are needed to draw definitive conclusions [25].

Strengths

This study has several strengths, particularly as the first systematic analysis of cannabis cessation apps. It adds to the growing body of research on alcohol, tobacco, and vaping cessation mobile apps and informs future research and practice in developing and analyzing cessation-focused apps. On the basis of our findings, we propose several recommendations for improving existing apps and developing future apps to better support the cessation process. Specifically, we suggest that researchers focus on providing adequate, evidence-based information for users and offering personalized experiences. Additionally, we recommend the use of multiple tools and methods to help facilitate cannabis cessation, including the use of artificial intelligence and apps that adapt to the users' moods and preferences [25]. This study lays the groundwork for further research on technology-based interventions, particularly mobile apps and chatbots, to help users quit cannabis.

Limitations

It is essential to acknowledge the limitations of this study. First, the small sample size limits the generalizability of the findings. However, this also demonstrates the need for further development of mHealth tools for cannabis use disorders. Furthermore, the evaluation of health care mobile apps is a recent endeavor, and thus, additional research is required to develop tools for accurate quality assessments. Additionally, given the rapid pace of mobile app development, it is possible that new apps released after our search were not captured in this review. Only free features were evaluated in this paper, as paid features were beyond the scope of this analysis. However, this approach was justified as free features and apps generally have larger audiences, higher use, and broader accessibility. The search was limited to the Canadian app stores, which could have possibly excluded apps available exclusively in other countries. Finally, the apps were analyzed only on Apple devices and not on Android devices. This meant some apps may not score comparatively on platforms running alternative operating systems. This was especially concerning as the apps were scored lower on the Google Play Store than on the Apple App Store.

Future Direction

Future research should be done to determine the clinical impact of these apps in regard to different users, ethnicities, and socioeconomic backgrounds. While usability and interface design were evaluated through the "Esthetics" and "Functionality" domains of the MARS analysis, the actual impact of these apps on the end users, particularly in promoting behavior change or supporting cannabis cessation, remains undetermined.

This study is the first to systematically evaluate freely available cannabis cessation mobile apps across major app platforms. Overall, this study found that the effectiveness and quality of currently available mobile apps for cannabis cessation are low, suggesting that more research is needed to develop evidence-based mobile apps for cannabis cessation. Unlike previous studies that focused on any apps associated with cannabis, this study particularly helps identify critical gaps in evidence-based content for mHealth interventions for cannabis cessation [21]. This study directly informs the need for the development of high-quality, evidence-based digital interventions and highlights the need for caution when patients use or clinicians recommend existing cannabis cessation apps. As cannabis use continues to rise globally, the creation and rigorous evaluation of mHealth apps may play a pivotal role in expanding access to effective cessation support and reducing cannabis-related harm.

Conclusions

This study identified and evaluated 4 mobile apps related to cannabis cessation. On the basis of the MARS analyses conducted, there is a critical gap in the current landscape of cannabis cessation mobile apps. The limited number of available apps, coupled with their low scores in the "information" category, underscores the need for more robust, scientifically tested digital interventions. As cannabis use and cannabis use disorders continue to rise globally, the development of high-quality mHealth tools may prove to be valuable in supporting the cessation process. Therefore, we recommend the development of more robust mobile apps that incorporate strong,

XSL•FO

evidence-based approaches to cannabis cessation, to better support individuals seeking to reduce or quit cannabis use.

Abstract

Background: Mobile health (mHealth) technologies are increasingly promoted as tools for chronic disease management and healthy aging, yet adoption remains persistently uneven across demographic groups. Japan, where 29.1% of the population is 65 years or older—the highest proportion globally—exemplifies the challenges of mHealth promotion in super-aging societies. Despite high smartphone penetration (90.1%) and active national digital transformation initiatives, only 21.6% of Japanese adults report regular mHealth app use, with marked disparities by age and sex.

Objective: This study examined determinants of mHealth acceptance by extending the unified theory of acceptance and use of technology to incorporate eHealth literacy, self-efficacy, perceived risk, distrust, and health-related factors (health status and health interest). Age- and sex-specific differences in acceptance mechanisms were also investigated using multigroup structural equation modeling (SEM).

Methods: We conducted a cross-sectional online survey in November 2023 with 960 Japanese adults sampled across 7 age strata (aged 18-27 years to aged ≥78 years). SEM tested hypothesized relationships among 9 constructs. Health status and health interest were included as observed covariates. Multigroup SEM with configural, metric, and structural invariance testing examined age- and sex-specific differences, and binary logistic regression identified predictors of current mHealth app use.

Results: The structural model demonstrated good fit (χ^2/df=2.06; comparative fit index 0.953; Tucker-Lewis index 0.945; root mean square error of approximation 0.047) and explained 71.6% of the variance in behavioral intention. Effort expectancy (β=0.404), facilitating conditions (β=0.349), and performance expectancy (β=0.188) were the primary proximal predictors of behavioral intention. Social influence exerted strong upstream effects on effort expectancy (β=0.811), eHealth literacy (β=0.507), and self-efficacy (β=0.422). Health interest positively influenced performance expectancy (β=0.133), whereas neither health interest nor health status showed a significant direct effect on distrust. Distrust did not directly predict behavioral intention in the overall sample. Multigroup analyses identified 5 significant age differences and 5 sex differences. eHealth literacy increased distrust among young adults but reduced perceived risk among middle-aged and older adults. Self-efficacy negatively predicted performance expectancy among young adults yet positively predicted it among middle-aged and older adults. Distrust significantly reduced behavioral intention only among middle-aged adults.

Conclusions: mHealth acceptance in Japan's aging society is characterized by stable proximal determinants of behavioral intention alongside heterogeneous upstream belief formation processes that vary systematically by age and sex. Health interest, rather than health status, emerged as the key contextual driver of perceived usefulness. At the theoretical level, this study clarifies

XSL•FO
RenderX

how eHealth literacy, self-efficacy, and distrust function as age- and sex-contingent antecedents within an extended unified theory of acceptance and use of technology framework. At the practical level, these findings highlight the need for trust-centered, demographically tailored, and literacy-sensitive strategies to promote equitable mHealth adoption in rapidly aging societies.

Introduction

Background

Mobile health (mHealth) technologies have emerged as critical tools for health care delivery, particularly in aging societies facing resource constraints and increasing chronic disease burdens [1,2]. Japan, with 29.1% of its population aged ≥65 years and projected to reach 38.4% by 2065 [3], exemplifies these demographic challenges [4]. Despite widespread smartphone penetration of 90.1% in 2022 and advanced digital infrastructure [5], mHealth adoption remains paradoxically low, with only 21.6% of Japanese adults reporting regular use of health-related apps [6,7]. This paradox reveals fundamental gaps in understanding technology acceptance mechanisms, particularly in aging populations where mHealth could deliver the greatest health benefits [8,9].

Existing technology acceptance research has predominantly examined younger, technologically proficient users in Western contexts [10,11], creating a critical knowledge gap regarding older adults' adoption mechanisms in rapidly aging Asian societies. Moreover, traditional technology acceptance models often overlook psychosocial factors specific to health technologies, privacy concerns [12,13], system distrust [14,15], and eHealth literacy [16,17], which may operate differently across age cohorts and cultural contexts. Understanding these age-differentiated, context-specific acceptance mechanisms is essential for designing evidence-based interventions to promote mHealth adoption among the world's fastest-aging populations [18,19].

Research Gaps and Theoretical Contributions

Despite extensive unified theory of acceptance and use of technology (UTAUT) applications to diverse technologies [20-22], several critical limitations persist in mHealth adoption research. Most existing studies have examined general populations or younger cohorts [23,24], with insufficient attention to older adults' distinct needs, capabilities, and concerns in aging societies where they constitute the primary target population for disease management apps yet demonstrate the lowest adoption rates [25,26]. In Japan's context, prior mHealth acceptance research has primarily focused on specific demographic segments to enable in-depth investigation. For example, Cao et al [27] examined mHealth acceptance among Japanese young adults using an extended UTAUT model, finding that trust, performance expectancy, and effort expectancy directly influenced behavioral intention, while health consciousness and social influence operated indirectly. Building upon these valuable insights, a comprehensive examination across the full adult lifespan within a single study remains needed to identify life stage–specific intervention strategies and enable population-level policy formulation [28,29].

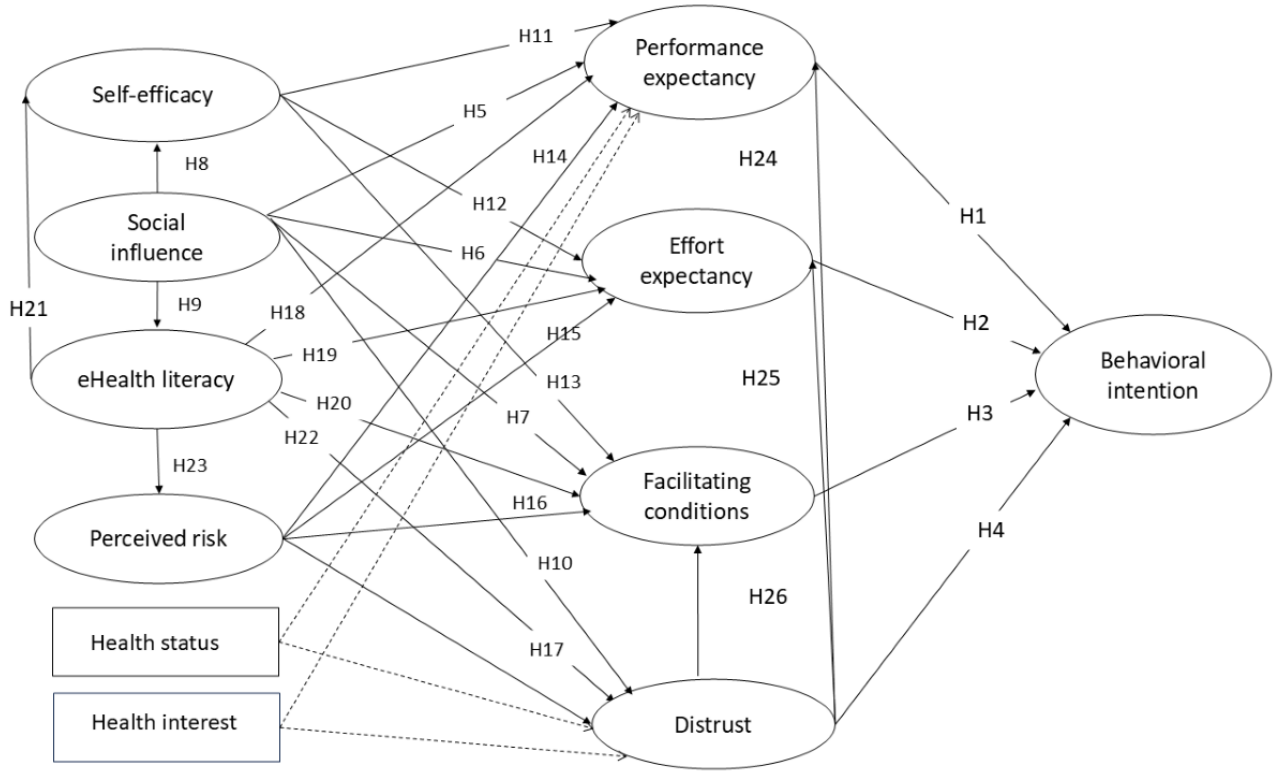
Furthermore, research rarely examines how acceptance mechanisms vary across demographic subgroups within the same population [30,31]. While some studies compare age or sex groups separately, few use rigorous multigroup structural equation modeling (SEM) to test whether theorized relationships operate identically across subgroups [32,33], preventing identification of demographic-specific barriers and facilitators [34,35]. Additionally, few studies distinguish between disease-management apps and wellness-oriented apps, despite potentially distinct adoption drivers [36,37].

This study complements existing research through 3 theoretical contributions. First, we integrate privacy-trust dimensions by incorporating perceived risk [25,38] and distrust [30,39] as distinct constructs—dimensions inadequately addressed in core UTAUT yet critical in health contexts involving sensitive personal data [40,41]. Importantly, we theorize distrust not merely as a direct barrier to behavioral intention but as a mediating mechanism undermining other acceptance perceptions, proposing that skepticism operates through both direct and indirect pathways [42,43]. This dual-pathway conceptualization advances prior research treating distrust solely as a direct predictor [14,30].

Second, we theorize eHealth literacy [16,17] as a multifaceted construct that simultaneously enhances acceptance perceptions while potentially increasing critical risk evaluation. This dual-function conceptualization challenges prevailing assumptions that digital literacy uniformly reduces barriers [44,45]. We hypothesize that eHealth literacy may paradoxically increase distrust among digitally sophisticated users capable of critical evaluation—an alternative mechanism unexplored in prior research [46,47].

Third, we extend UTAUT by theorizing social influence as a comprehensive distal predictor affecting not only core UTAUT constructs but also self-efficacy, eHealth literacy, and distrust [20,48,49]. This comprehensive pathway specification tests whether social influence operates through multiple mechanisms simultaneously—a theoretical proposition inadequately examined in prior research [20,48].

Theoretical Model and Research Hypotheses



Conceptual Framework

The theoretical model integrates core UTAUT constructs with privacy-trust dimensions and digital literacy constructs to comprehensively explain mHealth acceptance mechanisms

XSL•FO
RenderX

[20,50]. The model comprises 8 constructs organized into 3 layers: social influence, self-efficacy, perceived risk, and eHealth literacy function as distal predictors; performance expectancy, effort expectancy, facilitating conditions, and distrust serve as proximal predictors; and behavioral intention represents the outcome construct [51,52]. This multilayered specification enables examination of direct effects, indirect effects through mediation pathways, and total effects across demographic subgroups and app types [53,54]. Figure 1 presents the theoretical model with all hypothesized relationships.

Figure 1. Extended unified theory of acceptance and use of technology research model incorporating eHealth literacy, self-efficacy, perceived risk, distrust, and health-related covariates (H1-H26). Dotted lines indicate covariate effects.

Research Hypotheses

Based on UTAUT [20,50] and theoretical extensions [17,25,30], we propose 26 hypotheses specifying relationships among constructs [55,56].

- H1: performance expectancy positively influences behavioral intention to use mHealth apps [20,57]. Users perceiving greater health benefits demonstrate higher adoption intentions.
- H2: effort expectancy positively influences behavioral intention to use mHealth apps [20,57]. Users perceiving ease of use demonstrate higher adoption intentions.
- H3: facilitating conditions positively influence behavioral intention to use mHealth apps [20,57]. Users perceiving adequate infrastructure support demonstrate higher adoption intentions.
- H4: distrust negatively influences behavioral intention to use mHealth apps [30,58,59]. System skepticism directly discourages adoption.
- H5: social influence positively influences performance expectancy [20,48]. Social endorsements enhance perceived benefits through observational learning.
- H6: social influence positively influences effort expectancy [20,48]. Peer success experiences enhance ease-of-use perceptions.
- H7: social influence positively influences facilitating conditions [20,48]. Social networks provide information about support resources.
- H8: social influence positively influences self-efficacy [48,60]. Observing others' success enhances confidence through vicarious experience.
- H9: social influence positively influences eHealth literacy [48,49]. Social environments facilitate learning through knowledge exchange.
- H10: social influence negatively influences distrust [49]. Trusted endorsements reduce system skepticism through trust transfer.
- H11: self-efficacy positively influences performance expectancy [60,61]. Confident users anticipate successfully extracting maximum app value.
- H12: self-efficacy positively influences effort expectancy [60,61]. Confident users perceive technology tasks as less effortful.
- H13: self-efficacy positively influences facilitating conditions [60]. Confident users perceive support infrastructure as more adequate.
- H14: perceived risk negatively influences performance expectancy [25,38]. Privacy concerns introduce costs that offset anticipated benefits.

XSL•FO
RenderX

- H15: perceived risk negatively influences effort expectancy [25,38]. Privacy concerns increase perceived complexity through risk management burden.
- H16: perceived risk negatively influences facilitating conditions [38,62]. Privacy concerns signal potential infrastructure inadequacies.
- H17: perceived risk positively influences distrust [62,63]. Privacy concerns amplify general system skepticism.
- H18: eHealth literacy positively influences performance expectancy [16,17]. Digital health competencies enable informed benefit recognition.
- H19: eHealth literacy positively influences effort expectancy [16,17]. Digital literacy reduces learning curves through transferable skills.
- H20: eHealth literacy positively influences facilitating conditions [17,64]. Digital competencies expand perceived scope of adequate support.
- H21: eHealth literacy positively influences self-efficacy [16,64]. Digital health competencies enhance confidence through mastery experiences.
- H22: eHealth literacy negatively influences distrust [46,47]. Digital understanding may reduce skepticism, though sophisticated users may paradoxically identify system vulnerabilities.
- H23: eHealth literacy negatively influences perceived risk [44,45]. Digital knowledge enables accurate risk assessment that typically reduces threat overestimation.
- H24: distrust negatively influences performance expectancy [65,66]. Skepticism introduces doubts about whether promised benefits will materialize.
- H25: distrust negatively influences effort expectancy [65,66]. Skepticism elevates perceived complexity through suspicion of deliberately confusing design.
- H26: distrust negatively influences facilitating conditions [66,67]. Skepticism reduces confidence that adequate support truly exists.

Together, H24-H26 specify distrust's indirect pathways complementing the direct effect in H4, capturing how system skepticism operates through both immediate discouragement and systematic erosion of acceptance perceptions.

In addition, self-rated health status and health interest were incorporated as observed exogenous covariates predicting performance expectancy and distrust. This specification allows examination of whether perceived health condition and baseline health motivation shape core acceptance beliefs, thereby addressing the role of health-related need in mHealth adoption.

Research Objectives

This study pursued 3 objectives. First, we tested an extended UTAUT model incorporating perceived risk, distrust, eHealth literacy, and health-related covariates (health status and health interest), evaluating all 26 hypothesized relationships.

Second, we examined demographic heterogeneity by testing whether structural relationships differ across age groups (young adults aged 18-39 years, middle-aged adults aged 40-59 years, and older adults aged ≥60 years) and sex groups using multigroup SEM.

Third, we explored app-type-specific adoption mechanisms for different mHealth apps.

Hypotheses were specified for the overall model, whereas subgroup and app-type analyses were conducted as comparative extensions.

Methods

Ethical Considerations

This cross-sectional online survey study examined determinants of mHealth adoption in Japan's aging society between November 11 and 18, 2023. Ethical approval was obtained from the Waseda University Ethics Committee (number 2023-250), and the study complied with Japan's Act on the Protection of Personal Information [41]. Electronic informed consent was obtained from all participants through the online survey platform. Participants received a small number of reward points corresponding to approximately ¥10 or less than US $0.10 for completing the survey. No personally identifiable information was collected, and study reporting followed the CHERRIES (Checklist for Reporting Results of Internet E-Surveys; Multimedia Appendix 1) guidelines [68]. Survey data were stored on secure, password-protected servers accessible only to the research team and were exported to encrypted files for analysis. All analyses used deidentified data, and results are reported only in aggregate so that no individual participant can be identified.

Participants and Sampling

Sample size was determined using 2 approaches. For population estimation, normal approximation with finite-population correction for Japan (126 million) required a minimum n=385 (95% confidence; 5% margin of error; P=.50). For SEM (9 constructs; 31 indicators; 26 paths), a minimum n=310 was required (10:1 observations-to-parameters ratio) [69,70]. For multigroup analyses across 3 age groups and 2 sexes, 100 to 150 participants per subgroup ensured adequate power [32,33]. The target sample (N=960) exceeded all requirements and provided power >0.80 for detecting moderate effects (β≥0.20). Age was collected as a continuous variable (in years) and was also categorized into seven 10-year age strata for quota sampling and descriptive purposes.

Participants were recruited from the Cross Marketing, Inc (Tokyo, Japan) internet research panel using quota sampling across 7 age strata (18-27 years, 28-37 years, 38-47 years, 48-57 years, 58-67 years, 68-77 years, and ≥78 years) to ensure representation across the adult lifespan.

Of 23,434 invited panelists, a total of 2203 consented to participate. Data quality was ensured through multiple procedures, including the exclusion of responses with inconsistent demographic information and extremely short completion times. In addition, an attention-check item was embedded within the 5-point Likert scale questionnaire (eg, "Please select 'strongly agree' for this item"). Respondents who selected any option other than the instructed response were considered inattentive and excluded from the final sample.

XSL•FO
RenderX

After applying these criteria, a total of 960 valid responses were retained for analysis.

For inferential analyses, these 7 strata were collapsed into 3 theoretically meaningful groups: young adults (aged 18-39 years), middle-aged adults (aged 40-59 years), and older adults (aged ≥60 years), ensuring adequate statistical power for multigroup SEM. We chose 3 life-stage groups rather than all seven 10-year strata to avoid very small subgroup sizes, which would have produced unstable parameter estimates and less interpretable age-specific patterns in the SEM.

Participants were not required to have prior experience with mHealth apps, as the study assessed both behavioral intention and current use. However, all participants necessarily had internet access and basic digital literacy due to the online survey format.

Measurement Instruments

Participants reported demographic variables (age, sex, marital status, educational level, and current use of health monitoring apps). Technology acceptance constructs were measured using 9 established scales, each via 5-point Likert items (1=strongly disagree and 5=strongly agree). The following latent constructs were assessed: performance expectancy, effort expectancy, social influence, facilitating conditions, privacy risk, self-efficacy, distrust, behavioral intention, and eHealth literacy (eHealth Literacy Scale).

All survey items and their sources are provided in Table S1 in Multimedia Appendix 2. Items served as observed variables for latent constructs in SEM. Measurement validity and reliability were evaluated using confirmatory factor analysis (CFA).

Statistical Analysis

All analyses were performed using IBM SPSS Statistics (version 30) and IBM SPSS AMOS (version 30) [71]. Statistical significance was set at $P<.05$. Descriptive statistics summarized participant characteristics. Internal consistency was assessed using Cronbach α [72]. Multicollinearity was assessed using the variance inflation factor <5 [71,72].

CFA tested measurement validity, establishing adequacy via standardized factor loadings [72,73], average variance extracted (AVE≥0.50), and composite reliability (CR≥0.70). Discriminant validity was determined using the Fornell-Larcker criterion [72].

SEM using maximum likelihood estimation was performed to test hypothesized paths [71,74]. In the structural model, self-rated health status and health interest were specified as observed covariates predicting performance expectancy and distrust to account for individual differences in perceived health condition and baseline health motivation. Model fit was evaluated using multiple indices: $\chi^2/df<3$, CFI>.90, TLI>.90, goodness-of-fit index (GFI)>.90, adjusted GFI (AGFI)>.90, and root mean square error of approximation (RMSEA)≤.08 [72,73,75,76]. Descriptive statistics and inter-construct correlations appear in Table S2 in Multimedia Appendix 3.

Multi-group SEM examined sex and age differences with configural, metric, and structural invariance testing [32,33]. Chi-square difference tests ($\Delta\chi^2$) evaluated group differences [77,78]. Binary logistic regression analysis identified predictors of mHealth app use and behavioral intention by app type, reporting odds ratios (ORs) and 95% CIs [71,72]. Binary logistic regression analysis was used for app-specific use patterns because the outcome variable was dichotomous (current use vs nonuse) and the number of current users per app type was insufficient for stable SEM estimation (blood pressure: n=173; heart rate: n=118; physical activity: n=110). For the app-specific logistic regression analyses, construct scores were calculated as the mean scores of the corresponding questionnaire items and used as independent variables.

Results

Participant Characteristics

Among 960 valid respondents (476/960, 49.6% male; 484/960, 50.4% female; mean age 51.8, SD 17.8 years), participants were stratified into young adults (aged 18-39 years; 298/960, 31%), middle-aged adults (aged 40-59 years; 275/960, 28.6%), and older adults (aged ≥60 years; 387/960, 40.3%). For descriptive purposes, Table 1 reports age distributions across the original seven 10-year strata used for quota sampling, whereas subsequent inferential analyses (multigroup SEM and logistic regression) are based on the 3 life-stage groups (young adults, middle-aged adults, and older adults). Educational attainment was high, with university or graduate degrees representing the largest category (482/960, 50.2%), followed by high school graduates (272/960, 28.3%) and junior college graduates (156/960, 16.3%). Most participants were married (633/960, 65.9%), reported health interest (786/960, 81.9%), and self-assessed their health status as good or somewhat better (526/960, 54.8%).

eHealth Literacy

Table 2 provides the results on eHealth literacy by sex, age, and educational background.

The overall mean eHealth literacy score was 22.84 (SD 6.31). No significant sex differences were observed (male: 22.90, SD 6.72 and female: 22.79, SD 5.98), nor were there significant differences by educational level. However, age-related differences were identified, with participants aged 28-37 years (mean 24.42, SD 6.22) demonstrating the highest eHealth literacy scores, while those aged ≥78 years showed the lowest scores (mean 20.98, SD 6.14).

Descriptive Statistics for Study Constructs

Descriptive statistics (mean and SD) for all constructs and questionnaire items are provided in Table S2 in Multimedia Appendix 3. Across constructs, mean values for behavioral intention, distrust, and performance expectancy tended to be higher than for perceived risk and social influence, indicating broadly positive expectations for mHealth alongside some skepticism toward information reliability.

Current Use of mHealth Apps

Regarding mHealth use, a substantial majority (688/960, 71.7%) reported no current use, while 272/960 (28.3%) used at least 1 app. Among those, blood pressure monitoring showed the highest usage (173/960, 18.0%), followed by heart rate monitoring (118/960, 12.3%) and physical activity tracking (110/960, 11.5%). Detailed usage rates for each type of mHealth app are presented in Multimedia Appendix 4.

Usage patterns differed significantly by age group, with older adults demonstrating higher adoption of disease-management apps, while younger adults showed greater engagement with wellness-oriented apps.

Measurement Model Validation

Table 3 summarizes the convergent and discriminant validity indices (standardized loading ranges, AVE, CR, Cronbach α, maximum shared variance, and discriminant validity judgments) for all constructs included in the measurement model. The measurement model demonstrated satisfactory psychometric properties, with all standardized factor loadings exceeding 0.60 and most exceeding 0.70 (Table S3 in Multimedia Appendix 5 and Table S2 in Multimedia Appendix 3).

Convergent validity was supported, as most constructs achieved AVE values above the recommended threshold of 0.50. Self-efficacy and distrust were at the threshold level (approximately 0.50) but remained acceptable given their CR>0.70 and substantial factor loadings. To further address the marginal AVE values for self-efficacy and distrust, we estimated alternative CFA and structural models in which the lowest-loading indicator of each construct was removed. These reduced-item models yielded slightly higher AVE estimates and marginally improved fit indices (eg, CFI≈0.95; RMSEA≈0.05), but the overall pattern and significance of structural paths remained essentially unchanged. We therefore retained the original 3-item scales for self-efficacy and distrust in the main model to preserve content validity and comparability with prior research, while interpreting their structural effects with appropriate caution.

Discriminant validity was confirmed using the Fornell-Larcker criterion, as all constructs demonstrated AVE values greater than their maximum shared variance.

XSL•FO
RenderX

Table 3. Measurement model indices and discriminant validity (N=960). Discriminant validity was confirmed via the Fornell-Larcker criterion (average variance extracted [AVE] > maximum shared variance [MSV]). Detailed factor loadings are available in Table S2 in Multimedia Appendix 3. AVE values for self-efficacy and distrust were near the 0.50 threshold but were considered acceptable given composite reliability (CR) >0.70 and substantial factor loadings.

Construct	Standardized loading range	AVE	CR	Cronbach α	MSV	Discriminant validity
Self-efficacy	0.656-0.823	0.501	0.752	0.731	0.214	Supported
Social influence	0.767-0.824	0.644	0.844	0.871	0.54	Supported
Privacy risk	0.659-0.921	0.658	0.852	0.83	0.035	Supported
Performance expectancy	0.788-0.860	0.687	0.868	0.868	0.578	Supported
Effort expectancy	0.799-0.825	0.659	0.795	0.779	0.578	Supported
Distrust	0.612-0.773	0.5	0.749	0.739	0.035	Supported
Facilitating conditions	0.693-0.848	0.65	0.847	0.827	0.578	Supported
Behavioral intention	0.841-0.901	0.761	0.905	0.907	0.543	Supported
eHealth literacy	0.745-0.872	0.665	0.941	0.935	0.367	Supported

Overall Structural Model

The hypothesized extended UTAUT model is shown in Figure 1. The extended structural equation model including health interest and health status demonstrated good overall fit to the data: χ^2_{452}=932.4; *P*<.001; χ^2/df=2.1; GFI=0.889; AGFI=0.863; CFI=0.953; TLI=0.945; RMSEA=0.047 (90% CI 0.043-0.052). Although the chi-square statistic was statistically significant, which is common in large samples, the ratio of chi-square to degrees of freedom remained within an acceptable range. In addition, both incremental and absolute fit indices met or exceeded commonly recommended thresholds, indicating adequate model fit.

The structural model explained a substantial proportion of variance in behavioral intention (R^2=0.716). The explanatory power for endogenous constructs varied across variables, ranging from 0.4% for perceived risk to 82.1% for effort expectancy. Facilitating conditions (R^2=0.666) and performance expectancy (R^2=0.628) also showed substantial explained variance. These results indicate that the extended UTAUT framework provides strong explanatory power for mHealth acceptance in the study sample.

The structural path coefficients for the overall sample are presented in Table 4.

Effort expectancy exerted the strongest positive effect on behavioral intention (β=0.404; *P*<.001), followed by facilitating conditions (β=0.349; *P*<.001) and performance expectancy (β=0.188; *P*<.001), supporting H1-H3. In contrast, distrust did not have a statistically significant effect on behavioral intention (β=−0.027; *P*=.45); therefore, H4 was not supported. Together, these findings indicate that perceived ease of use, infrastructural support, and expected health benefits are the primary proximal determinants of mHealth adoption intention in the overall sample, while distrust does not exert a direct influence.

Social influence emerged as the most powerful distal predictor in the model. It showed strong positive effects on effort expectancy (β=0.811; *P*<.001), facilitating conditions (β=0.548; *P*<.001), and performance expectancy (β=0.662; *P*<.001), supporting H5-H7. Social influence also significantly enhanced self-efficacy (β=0.422; *P*<.001) and eHealth literacy (β=0.507; *P*<.001), supporting H8 and H9. In addition, social influence significantly reduced distrust (β=−0.248; *P*<.001), supporting H10. These results indicate that social environments strongly shape perceptions of usefulness, ease of use, infrastructural support, digital competencies, and trust in mHealth technologies.

eHealth literacy demonstrated a complex pattern of effects. Higher eHealth literacy significantly improved facilitating conditions (β=0.323; *P*<.001), self-efficacy (β=0.204; *P*<.001), performance expectancy (β=0.097; *P*=.04), and effort expectancy (β=0.164; *P*<.001), supporting H18-H21. However, it did not significantly reduce perceived risk (β=−0.063; *P*=.21), leading to rejection of H23. Notably, eHealth literacy increased distrust (β=0.150; *P*=.02), yielding a statistically significant but directionally reversed effect relative to H22. These findings suggest that individuals with higher digital health competencies may develop a more critical awareness of potential risks and limitations in digital health systems.

Perceived risk consistently undermined acceptance-related perceptions. It significantly increased distrust (β=0.265; *P*<.001), supporting H17, and negatively affected facilitating conditions (β=−0.112; *P*=.003), effort expectancy (β=−0.117; *P*=.002), and performance expectancy (β=−0.079; *P*=.04), supporting H14-H16. These findings indicate that privacy and security concerns simultaneously increase distrust while reducing perceived usefulness, ease of use, and infrastructural support for mHealth technologies.

Self-efficacy did not exhibit significant direct effects on the core UTAUT constructs in the overall model. Its paths to performance expectancy (β=0.100; *P*=.06), effort expectancy (β=−0.022; *P*=.67), and facilitating conditions (β=0.046; *P*=.37) were not significant, and therefore H11-H13 were not supported. These results suggest that self-efficacy primarily functions as an outcome of social influence and eHealth literacy rather than as a direct determinant.

Distrust showed limited direct effects. It did not significantly influence effort expectancy (β=0.003; *P*=.94) or performance expectancy (β=−0.017; *P*=.70); therefore, H25 and H24 were not supported. Contrary to H26, distrust showed a small but significant positive effect on facilitating conditions (β=0.125; *P*=.006), indicating that the predicted negative relationship was not confirmed; therefore, H26 was not supported. This unexpected direction suggests that distrust may prompt compensatory information-seeking behavior rather than withdrawal from support structures.

Health-related covariates showed selective effects. Health interest significantly increased performance expectancy (β=0.133; *P*<.001), indicating that individuals with greater health interest perceive higher utility in mHealth technologies. In contrast, self-rated health status did not significantly influence performance expectancy (β=−0.016; *P*=.64), and neither health interest nor health status significantly predicted distrust (β=−0.054; *P*=.29 and β=0.049; *P*=.33, respectively). These covariate effects were included for control purposes and were not part of the formal hypothesis testing framework.

Sex-Stratified Analysis

The multigroup structural equation model for sex demonstrated acceptable to good model fit. The chi-square statistic was significant (χ^2_{904}=1994.9; *P*<.001), which is expected given the large sample size; however, the ratio of chi-square to degrees of freedom was within an acceptable range (χ^2/df=2.21).

Incremental fit indices indicated good model fit (CFI=0.944; TLI=0.935; incremental fit index (IFI)=0.944). The RMSEA value was 0.035 (90% CI 0.033-0.038; P_{close}>.99), indicating excellent fit. Although the GFI (0.882) and AGFI (0.853) were slightly below the conventional threshold, these indices are known to be sensitive to sample size and model complexity.

Overall, these results suggest that the model provides a satisfactory representation of the data and is appropriate for subsequent multigroup comparisons by sex.

The explanatory power of the model remained high across sex groups. The model explained a substantial proportion of variance in behavioral intention, accounting for 71.7% of the variance among males and 70.1% among females. Sex-stratified structural path coefficients are presented in Table 5.

First, social influence significantly reduced distrust among males (β=−0.325; *P*<.001) but not among females (β=−0.100; *P*=.16; $\Delta\chi^2$=5.7; *P*=.02). This finding indicates that normative social cues function as more effective trust-building mechanisms for male users.

Second, eHealth literacy significantly reduced perceived risk among females (β=−0.210; *P*<.001) but not among males (β=−0.080; *P*=.11; $\Delta\chi^2$=5.2; *P*=.02). This suggests that digital health competencies play a stronger role in mitigating privacy and security concerns among women.

Third, distrust exerted significantly stronger effects on effort expectancy among females (β=0.287; *P*<.001) than among males (β=0.031; *P*=.48; $\Delta\chi^2$=17.3; *P*<.001). This indicates that distrust more strongly shapes perceived ease of use among female users.

Fourth, distrust also had a significantly stronger effect on performance expectancy among females (β=0.226; *P*<.001) than among males (β=−0.020; *P*=.65; $\Delta\chi^2$=12.6; *P*<.001), suggesting that distrust influences perceived usefulness primarily among women.

Fifth, performance expectancy exerted significantly stronger effects on behavioral intention among females (β=0.388; *P*<.001) than among males (β=0.200; *P*<.001; $\Delta\chi^2$=4.0; *P*=.04). These results indicate that perceived health benefits constitute a more central driver of mHealth adoption intentions for female users.

In contrast, no significant sex difference was observed for the path from distrust to behavioral intention ($\Delta\chi^2$=1.7; *P*=.19), although the effect was statistically significant only among females.

Age-Stratified Analysis

For age-stratified multigroup SEM, participants were categorized into 3 groups: young adults (aged 18-39 years; n=298), middle-aged adults (aged 40-59 years; n=275), and older adults (aged ≥60 years; n=387).

The multigroup structural equation model across the 3 age groups demonstrated acceptable to good fit: χ^2_{1356}=2762.4; *P*<.001; χ^2/df=2.04; GFI=0.849; AGFI=0.812; normed fit index 0.871; CFI=0.929; TLI=0.917; IFI=0.930; RMSEA=0.033 (90% CI 0.031-0.035; P_{close}>.99).

Although GFI and AGFI were slightly below the conventional threshold of 0.90, these indices are known to be sensitive to model complexity and sample size. In contrast, incremental fit indices (CFI, TLI, and IFI) exceeded recommended thresholds, and RMSEA indicated excellent model fit. Taken together, these results suggest that the age-stratified model provides an adequate and robust representation of the observed data.

The explanatory power of the model remained high across age groups. The model explained 77.1% of the variance in behavioral intention among young adults, 67.5% among middle-aged adults, and 69.1% among older adults (Table 6).

First, social influence exerted significantly different effects on performance expectancy across age groups ($\Delta\chi^2_2$=11.76; *P*<.01). The effect was strongest among young adults (β=0.919; *P*<.001), followed by middle-aged adults (β=0.617; *P*<.001) and older adults (β=0.574; *P*<.001), indicating that social cues play a more prominent role in shaping perceived usefulness among younger individuals.

Second, eHealth literacy showed significant age differences in its effect on perceived risk ($\Delta\chi^2_2$=13.7; *P*<.01). Specifically, eHealth literacy significantly reduced perceived risk among middle-aged adults (β=−0.187; *P*=.005) and older adults (β=−0.231; *P*<.001), whereas no significant association was observed among young adults (β=0.061; *P*=.36). This suggests that digital health competencies function as a risk-mitigating factor primarily in older populations.

Third, self-efficacy exhibited the largest age-related heterogeneity in its effect on performance expectancy ($\Delta\chi^2_2$=17.1; *P*<.001). Notably, self-efficacy negatively influenced performance expectancy among young adults (β=−0.324; *P*<.001), while showing positive effects among middle-aged adults (β=0.161; *P*=.02) and older adults (β=0.110; *P*=.05). This reversal suggests that confidence in one's digital abilities may lead to more critical evaluations of mHealth usefulness among younger users.

Fourth, distrust demonstrated significant age differences in its effect on effort expectancy ($\Delta\chi^2_2$=13.5; *P*<.01). Distrust strongly increased perceived difficulty of use among young adults (β=0.349; *P*<.001), whereas this relationship was not significant among middle-aged adults (β=0.075; *P*=.22) or older adults (β=0.039; *P*=.37).

Fifth, distrust also showed significant age differences in its effect on performance expectancy ($\Delta\chi^2_2$=10.7; *P*<.01). Distrust positively influenced performance expectancy among young adults (β=0.249; *P*<.001), while no significant effects were observed among middle-aged adults (β=−0.002; *P*=.97) or older adults (β=0.022; *P*=.66), indicating divergent interpretations of distrust across age groups.

In contrast, no significant age differences were observed in the effects of performance expectancy ($\Delta\chi^2_2$=1.7; *P*>.05), facilitating conditions ($\Delta\chi^2_2$=3.6; *P*>.05), or distrust ($\Delta\chi^2_2$=9.1; *P*>.01) on behavioral intention, and age differences in the direct effect of distrust on behavioral intention were confined to middle-aged adults. Thus, while distrust showed some age-contingent influence on intention, the core positive determinants of mHealth adoption (performance expectancy, effort expectancy, and facilitating conditions) remained largely invariant across age groups.

These findings indicate that the proximal determinants of mHealth adoption intention are largely invariant across age groups, despite substantial heterogeneity in upstream cognitive and perceptual mechanisms. Health-related covariates showed a consistent pattern across age groups. Health interest significantly increased performance expectancy in all 3 age groups (young adults: β=0.133; *P*=.002; middle-aged adults: β=0.090; *P*=.05; older adults: β=0.202; *P*<.001), with the strongest effect among older adults, whereas self-rated health status did not significantly predict performance expectancy or distrust in any group.

App-Specific Use Patterns: Binary Logistic Regression Analysis

Binary logistic regression analysis examined predictors of current use across 3 app types: blood pressure monitoring (n=173), heart rate monitoring (n=118), and physical activity tracking (n=110), using the original 7 age strata as categorical predictors. All models demonstrated adequate fit (Hosmer-Lemeshow $P>.05$) with a Nagelkerke R^2 of 0.14 for each model. Table 7 presents ORs and 95% CIs.

Table 7. App-specific predictors of current mHealth use.

[a]OR: odds ratio.
[b]$P<.05$.
[c]$P<.001$.
[d]$P<.01$.

Behavioral intention and eHealth literacy emerged as consistent significant predictors across all 3 app types. For blood pressure monitoring, behavioral intention (OR 1.40, 95% CI 1.08-1.80; $P=.01$) and eHealth literacy (OR 1.85, 95% CI 1.42-2.42; $P<.001$) significantly predicted current use. Sex was not a significant predictor (OR 0.74, 95% CI 0.52-1.05). Age demonstrated a pronounced gradient compared with users aged 18-27 years, those aged 58-67 years (OR 2.34, 95% CI 1.18-4.61; $P=.02$), aged 68-77 years (OR 3.15, 95% CI 1.63-6.12; $P<.001$), and aged ≥78 years (OR 3.76, 95% CI 1.93-7.32; $P<.001$) exhibited substantially elevated odds of use, reflecting the clinical relevance of hypertension management among older populations.

For heart rate monitoring, behavioral intention (OR 1.77, 95% CI 1.30-2.41; $P<.001$) and eHealth literacy (OR 1.84, 95% CI 1.35-2.53; $P<.001$) significantly predicted current use. Sex was not significant (OR 0.89, 95% CI 0.59-1.33). Age effects were less pronounced than for blood pressure monitoring, with only users aged 68-77 years demonstrating significantly elevated odds (OR 2.37, 95% CI 1.15-4.89; $P=.02$), suggesting broader age-range appeal for heart rate monitoring compared with blood pressure monitoring.

Physical activity tracking demonstrated the strongest behavioral intention effect among the 3 apps (OR 2.47, 95% CI 1.76-3.47; $P<.001$), with eHealth literacy also significantly predicting use (OR 1.57, 95% CI 1.14-2.17; $P=.006$). Sex (OR 0.82, 95% CI 0.54-1.25) and all age groups showed no significant differences compared with the reference group, indicating cross-demographic adoption patterns driven by intrinsic

XSL•FO
RenderX

motivation and digital health competency rather than age-related clinical necessity.

Discussion

Overview

This study examined the determinants of mHealth acceptance in Japan using an extended UTAUT framework that incorporated distrust, perceived risk, and eHealth literacy, while additionally modeling health status and health interest as covariates of performance expectancy and distrust. Overall, the findings confirmed the central role of the core UTAUT constructs—performance expectancy, effort expectancy, and facilitating conditions—in shaping behavioral intention, while also demonstrating that demographic heterogeneity in Japan is concentrated primarily in upstream cognitive and evaluative processes rather than in the final intention-formation stage [20-22,50,52,54,55]. This distinction is important because it suggests that the basic decision logic of mHealth acceptance is relatively stable, even in a superaged society, whereas the pathways through which individuals form beliefs about usefulness, ease of use, trust, and risk differ substantially by age and sex.

Principal Findings and Theoretical Contributions

Consistent with prior UTAUT-based research, performance expectancy, effort expectancy, and facilitating conditions emerged as robust predictors of behavioral intention in the overall model [20-22,50,52,54,55,79]. This pattern is also broadly consistent with earlier studies on mHealth adoption among older adults and chronic disease populations [23,24,28,29]. However, this study extends this literature by showing that, although these proximal determinants remain central, age differences were not statistically significant for the direct effects of performance expectancy and facilitating conditions on behavioral intention. This suggests that the core decision structure linking beliefs to intention may be more stable across the life course than is often assumed. Put differently, age appears to matter less for how people translate beliefs into intention than for how those beliefs are initially formed.

A major theoretical contribution of this study is the expanded role of social influence. In conventional UTAUT, social influence is usually modeled as one determinant of intention or belief formation [20,21]. In this study, however, social influence exerted broad and upstream effects on eHealth literacy, self-efficacy, performance expectancy, effort expectancy, and facilitating conditions, while also reducing distrust. This broader role exceeds many Western UTAUT applications [20,22] and is consistent with the Japanese context, where family members, peers, and health care professionals often function as key agents of reassurance, persuasion, and health-related decision support [18,19,27]. The age-stratified analyses further showed that the effect of social influence on performance expectancy was strongest among young adults. This finding suggests that, in contemporary Japan, younger users may evaluate the usefulness of mHealth partly through socially mediated expectations and peer-based information environments rather than solely through individual instrumental reasoning. In this sense, social influence in Japan may operate not only as a normative force but also as a mechanism of informal digital health education.

A second major contribution concerns eHealth literacy. Previous studies have generally positioned eHealth literacy as a uniformly beneficial facilitator of digital health use [16,17,45,46,64,80-82]. In Japan, the Japanese eHealth Literacy Scale has demonstrated strong internal consistency and construct validity in a large internet-based survey, with higher scores among middle-aged adults and frequent internet users [83]. Our results support this view only partially. Among middle-aged and older adults, higher eHealth literacy significantly reduced perceived risk, which is consistent with both international research and Japanese evidence linking eHealth literacy to improved health knowledge and screening-related practices [16,17,64]. However, this pattern did not extend to younger adults. In the younger group, eHealth literacy did not reduce perceived risk and was accompanied by more critical appraisals in related pathways. This suggests that eHealth literacy is better conceptualized as a context-dependent cognitive resource: it may reduce uncertainty in populations with lower baseline digital familiarity, but among digitally experienced users, it may instead sharpen awareness of privacy vulnerability, data misuse, or functional limitations. This interpretation aligns with research on the privacy paradox and digitally engaged patients [12,25,47,84,85].

A third theoretical contribution lies in the age-differentiated role of self-efficacy. In many prior studies, self-efficacy has shown positive associations with perceived usefulness and ease of use [20,57,60,61]. In this study, however, self-efficacy did not significantly predict performance expectancy, effort expectancy, or facilitating conditions in the overall model, and age-stratified analyses revealed a more complex pattern. Most notably, self-efficacy negatively predicted performance expectancy among younger adults but positively predicted it among middle-aged and older adults. This reversal suggests that digitally confident younger users may hold higher expectations for digital services and therefore evaluate mHealth apps more critically when the apps fail to meet their standards, whereas among middle-aged and older adults, self-efficacy plays the more conventional enabling role by lowering psychological barriers and making benefits more salient [23,26,28]. At the same time, the weak direct effect of self-efficacy in the overall model and its conceptual proximity to eHealth literacy indicate that self-efficacy in mHealth acceptance may operate more indirectly and contextually than previous models assume, partly overlapping with eHealth literacy as a mediating cognitive resource [16,17,64,82].

A fourth contribution is the clearer differentiation between distrust and perceived risk. Prior information systems and digital health research have often linked trust, distrust, and risk closely, but not always modeled them as distinct pathways [12-15,30,39,42,58,59,62,63]. In this study, perceived risk and distrust behaved differently. Perceived risk consistently undermined acceptance-related beliefs, whereas distrust showed selective and demographically contingent effects. In the overall model, distrust did not significantly reduce behavioral intention, but it influenced effort expectancy and performance expectancy in subgroup analyses, particularly among women and younger adults. These findings suggest that distrust should not be reduced

XSL•FO
RenderX

to a mere proxy for perceived risk. Rather, distrust appears to function as a broader evaluative orientation toward the technology, platform, or data environment, while perceived risk reflects a more specific anticipation of privacy or security harm [14,30,58,59]. This conceptual separation is valuable for digital health research, where users may simultaneously recognize objective risks and still maintain—or fail to maintain—confidence in the system's legitimacy and safety [12,13,40-43,86,87]. Consistent with the additional reduced-item models, the selective and mainly indirect role of distrust appears to be driven more by its structural position in the extended UTAUT framework than by weaknesses in the measurement model, reinforcing the need to interpret distrust as a nuanced, context-dependent barrier rather than a uniformly dominant deterrent to mHealth adoption.

Contrary to H26, distrust showed a small but significant positive effect on facilitating conditions. This unexpected finding may reflect compensatory information-seeking behavior, whereby skeptical users actively engage with available support structures to verify system safety rather than withdrawing from them [88]. In addition, the strong role of social influence and the differentiated effects of distrust are congruent with culturally specific notions such as sekentei (concern for social evaluation) and anshin (sense of safety and peace of mind), which shape how Japanese users balance institutional assurances, peer endorsement, and perceived vulnerability when deciding whether to adopt mHealth services [89,90].

Sex and Age Heterogeneity in the Japanese Context

The sex-stratified results revealed systematic, rather than incidental, heterogeneity. Compared with women, men showed a stronger negative pathway from social influence to distrust, suggesting that social endorsement and interpersonal reassurance play a larger role in trust formation among male users. By contrast, women showed a stronger negative pathway from eHealth literacy to perceived risk and a stronger positive pathway from performance expectancy to behavioral intention. These findings are broadly consistent with prior research suggesting that women are more attentive to privacy, risk, and benefit evaluation in digital contexts, whereas men may rely more heavily on social and structural cues [31,79,90]. In the Japanese context, this implies that male users may respond particularly well to social endorsement and visible legitimacy, whereas female users may be more influenced by the extent to which a system appears beneficial, transparent, and safe.

The age-stratified results were especially informative. Significant age differences were identified in the pathways from social influence to performance expectancy, eHealth literacy to perceived risk, self-efficacy to performance expectancy, and distrust to both effort expectancy and performance expectancy. In contrast, no statistically significant age differences were observed in the direct effects of performance expectancy or facilitating conditions on behavioral intention. This pattern strongly suggests that age-related heterogeneity in Japan is concentrated in the formation of beliefs rather than in the final translation of those beliefs into adoption intention.

Among young adults, social influence had the strongest effect on performance expectancy, and distrust significantly affected both effort expectancy and performance expectancy. This suggests that younger users do not simply accept or reject mHealth technologies based on distrust alone; rather, distrust may stimulate more active evaluation of usability and utility. Such a pattern is compatible with the idea of "informed skepticism," in which digitally experienced users are not necessarily more trusting, but instead more critical and selective [12,47,79,84]. Among middle-aged adults, eHealth literacy reduced perceived risk, and self-efficacy positively influenced performance expectancy, suggesting a more instrumental and balanced evaluative style. This may reflect the life-stage demands of work, family responsibility, and health management, which make reliability and usefulness especially salient. This interpretation is also consistent with recent Japanese evidence showing that mHealth adoption among workers is associated with health-related motivations and daily-life relevance [7]. Among older adults, eHealth literacy also reduced perceived risk, but distrust no longer affected behavioral intention. This suggests that older adults may rely more on literacy-based reassurance and practical value than on distrust-sensitive rejection. Rather than indicating a simple deficit, this pattern implies a functional reorganization of evaluation in later life, consistent with earlier studies emphasizing usability support, family assistance, and the need for age-sensitive design [9,23,26,28,82,91].

Taken together, these findings help explain a persistent Japanese paradox. Japan is characterized by high life expectancy, universal health coverage, extensive digital infrastructure, and rapid population aging, yet mHealth adoption remains limited [3-7]. Our results suggest that this underuse is not explained simply by a lack of infrastructure or a universal failure of perceived usefulness. Rather, it stems from demographic differences in how usefulness, trust, literacy, and risk are interpreted and weighted. In that sense, this study extends prior Japanese work by moving from a descriptive discussion of barriers to a structural account of how those barriers are organized within the acceptance process.

Health-Related Covariates and Contextual Interpretation

An important addition prompted by the revision process was the inclusion of health status and health interest as covariates of performance expectancy and distrust. These analyses strengthened the interpretation of the model in meaningful ways. Health interest positively predicted performance expectancy in the overall model and across sex and age subgroups, with particularly strong effects among older adults. This indicates that users who are more concerned about their health are more likely to perceive mHealth technologies as beneficial. This result is intuitively plausible and aligns with earlier research suggesting that health motivation is a key antecedent of engagement with preventive and self-management applications [1,36,37].

By contrast, self-rated health status showed weaker and less consistent effects. It did not significantly predict performance expectancy in the overall model or across most subgroups, although in some subgroup analyses it was associated with lower distrust. These findings suggest that subjective health concern

XSL•FO
RenderX

may be a more important driver of acceptance-related beliefs than objective or self-perceived health condition per se. This is a useful refinement of the "clinical necessity" argument: it is not simply being less healthy that matters, but being more attentive to one's health and more motivated to manage it. Accordingly, claims about "pragmatic acceptance" among older adults should be interpreted in relation to health interest and literacy rather than assumed solely from age or illness burden.

App-Type Specificity

The app-type-specific analyses further emphasized that mHealth adoption is not monolithic. Disease-management apps were more strongly associated with older adults and with contexts of clinical necessity, consistent with prior telemonitoring and chronic disease management studies [2,37,80,81,92,93]. By contrast, wellness and physical activity apps showed broader cross-demographic appeal and appeared to be driven more by behavioral engagement than by medical need [1,36,37]. This distinction is important because it implies that "performance expectancy" may not mean the same thing across app categories. In disease management, perceived usefulness is likely tied to symptom control, physician recommendation, and safety; in wellness apps, it may reflect motivation, convenience, enjoyment, or self-optimization [1,36,44,56]. Future models of mHealth acceptance should therefore be more explicit about app context rather than assuming that adoption mechanisms are uniform across all digital health tools.

Practical Implications

Several practical implications follow. First, trust-centered strategies are essential. Because distrust and perceived risk operate differently across demographic groups, improving app functionality alone will not be sufficient. Transparent data governance, visible compliance with privacy regulations, third-party security certification, and clear communication about data use are especially important in the Japanese setting, where public sensitivity to personal information protection remains high [12,13,25,40,41,86,87].

Second, interventions should combine universal and targeted strategies. Universal approaches can focus on improving performance expectancy, effort expectancy, and facilitating conditions, because these remain stable predictors of intention across age groups. However, upstream mechanisms require tailoring. For younger users, transparent governance and user control may be more effective than generic promotional messages. For middle-aged users, interventions should emphasize practical value, reliability, and low-risk integration into everyday life. Even among digitally reachable older adults with relatively high eHealth literacy, digital literacy support, simplified interfaces, and family- or community-assisted onboarding remain important for sustaining engagement, while interventions targeting offline or low-connectivity seniors will require additional outreach and support mechanisms [9,23,26,28,82].

Third, implementation in Japan should make explicit use of interpersonal and institutional actors. The structural breadth of social influence observed in this study indicates that peers, family members, workplaces, and health care professionals are not merely dissemination channels but active components of the acceptance process [18,19,27]. This has implications for public health campaigns, workplace wellness programs, and physician-endorsed disease management systems.

Limitations and Future Research

Several limitations should be noted. First, the study relied on an online panel, which likely underrepresents individuals with limited internet access or lower digital engagement, especially among older adults [68,94]. Accordingly, the older group in this study should be interpreted primarily as digitally reachable older adults rather than as fully representative of the Japanese older population as a whole. In our sample, the mean eHealth literacy score was 22.84 (SD 6.31), which is somewhat higher than the 20.46 (SD 5.64) reported in a recent Japanese internet-based study using the eHealth Literacy Scale in a public health context [83]. Because both studies relied on online samples, these values likely overestimate eHealth literacy in the broader Japanese population, particularly among offline or low-connectivity seniors. Relative to the broader Japanese population, nondigital seniors may have lower eHealth literacy, greater usability barriers, and stronger dependence on facilitating conditions, meaning that the present findings may underestimate acceptance barriers in the most vulnerable groups. Future research should therefore use mixed-mode survey designs and community-based recruitment strategies—such as outreach through local clinics, senior centers, and home-visit services—to reach digitally excluded older adults who are absent from online panels and to better capture their acceptance mechanisms and support needs. Although our overall structural model showed acceptable fit according to incremental and parsimony-adjusted indices (CFI=0.953; TLI=0.945; RMSEA=0.047), the GFI (0.889) and AGFI (0.863) fell slightly below the conventional 0.90 threshold specified in the Methods section. Given the well-performing CFI, TLI, and RMSEA values and the known sensitivity of GFI and AGFI to sample size and model complexity, we interpret the structural model as adequately fitting while acknowledging this limitation.

Second, the cross-sectional design precludes causal inference and limits our ability to distinguish age-related differences from cohort or period effects [95]. Third, although the model explained a substantial proportion of variance in behavioral intention, future research should incorporate actual usage behavior and longitudinal follow-up to distinguish initial intention from sustained engagement [1,36,44,56]. Fourth, while this study identified meaningful age- and sex-related heterogeneity, future work should continue to test measurement robustness and explore whether similar structural patterns hold in other East Asian contexts or in more clinically specific populations [32-35,77,78]. Finally, because habit and hedonic motivation were not included, future research focusing on established users should examine whether UTAUT2 constructs become more relevant in later stages of mHealth engagement [50,56].

Conclusion

This study provides robust empirical evidence that mHealth acceptance in Japan's aging society is shaped by a dual structure consisting of stable proximal determinants and heterogeneous

XSL•FO
RenderX

upstream belief-formation processes. While performance expectancy, effort expectancy, and facilitating conditions consistently predict behavioral intention across demographic groups, age and sex differences emerge primarily in how these beliefs are constructed through social influence, eHealth literacy, distrust, and perceived risk.

By extending the UTAUT framework to incorporate distrust, perceived risk, and eHealth literacy, and by integrating health status and health interest as contextual covariates, this study advances the theoretical understanding of digital health acceptance beyond conventional models. In particular, the findings demonstrate that eHealth literacy functions as a context-dependent cognitive resource, self-efficacy exhibits age-contingent effects—including a reversal pattern among younger users—and distrust operates through distinct mechanisms that are not reducible to perceived risk. These results challenge the assumption of uniform acceptance mechanisms and highlight the importance of distinguishing between belief formation and intention formation.

From a policy and practice perspective, the findings indicate that universal promotion strategies for mHealth are insufficient in aging societies. Instead, effective implementation requires trust-centered, demographically tailored, and context-sensitive approaches. For younger users, strategies should address informed skepticism through transparency and user control; for middle-aged users, emphasis should be placed on practical value and risk mitigation; and for older adults, interventions should prioritize literacy support, usability, and social or familial facilitation.

In the Japanese context—characterized by rapid population aging, advanced digital infrastructure, and strong institutional health care systems—these differentiated mechanisms help explain the persistent gap between technological availability and actual mHealth use. Addressing this gap requires not only improving technological functionality but also strengthening trust, enhancing digital health literacy, and leveraging social and institutional support structures.

Overall, this study contributes to the growing literature on digital health by demonstrating that mHealth acceptance is fundamentally shaped by the interaction of psychological, social, and demographic factors. Future research should further examine longitudinal adoption patterns, incorporate behavioral usage data, and explore culturally specific constructs to refine theory and inform more effective digital health interventions in aging societies.

Abstract

Background: With the rapid proliferation of mobile health (mHealth) apps in clinical practice, ensuring their usability for health care providers is critical to optimize workflow integration and service delivery. The mHealth App Usability Questionnaire (MAUQ) is a validated tool for assessing usability, but its applicability in Chinese health care settings remains untested. Cross-cultural adaptation and validation of the MAUQ for interactive apps are essential to address this gap.

Objective: This study aimed to translate the MAUQ (for interactive apps for health care providers) into Chinese (MAUQ-C), adapt it to the Chinese health care context, and validate its psychometric properties for future mHealth research and use in China.

Methods: This cross-sectional study followed international guidelines for cross-cultural adaptation, including forward translation, backward translation, expert review, and pretesting. A convenience sample of 382 health care providers (eg, physicians and nurses) using mHealth apps was recruited from 2 hospitals in China. Reliability was evaluated using the Cronbach α, test-retest reliability, and split-half reliability. Validity was assessed through content validity index, exploratory factor analysis, and confirmatory factor analysis.

Results: The MAUQ-C retained the original 21-item structure and 3 dimensions. Content validity index values ranged from 0.833 to 1.000 (Scale-Content Validity Index/Average=0.992). Exploratory factor analysis identified a 3-factor model explaining 63.48% of the total variance. Confirmatory factor analysis confirmed a good model fit (minimum discrepancy/df=1.810; cumulative fit index=0.950; root-mean-square error of approximation=0.058). The Cronbach α for the total scale was 0.919, with dimension-specific values of 0.928, 0.877, and 0.886. Test-retest reliability was 0.881, and split-half reliability was 0.726. These results confirm that the MAUQ-C effectively measures usability across the dimensions of usability and satisfaction, system information arrangement, and efficiency.

Conclusions: The MAUQ-C is a reliable and valid instrument for evaluating mHealth app usability among Chinese health care providers. It can serve as a critical tool to guide the development and optimization of mHealth solutions tailored to the Chinese health care system.

Introduction

The substantial user base for internet medical services of 418 million by 2024 in China provides a critical foundation for mobile health (mHealth) [1]. The World Health Organization defines mHealth as the "medical and public health practice supported by mobile devices, such as mobile phones, patient monitoring devices, personal digital assistants, and other wireless devices" [2]. Driven by advancing public health literacy and internet technology, this sector has experienced explosive growth and become extensively integrated into personal health management ecosystems [3,4], where mHealth apps typically offer multifaceted functionalities, including monitoring and recording health data, disease management [5], and medical guidance [6], among others [7].

However, nearly half a million mHealth apps developed remain underused [8], largely due to the absence of effective usability evaluations. This gap contributes to skepticism among clinicians, scholars, and patients regarding the reliability of mHealth programs [9]. High-usability mHealth apps typically exhibit 5 core attributes: efficiency, favorable user perception, ease of learning, memorability, and low error rates [10]. While usability questionnaires remain the predominant method for evaluating usability, the most commonly used instruments—such as the System Usability Scale (SUS) and Post-Study System Usability Questionnaire (PSSUQ) [11]—are primarily designed for expert-based objective evaluation, not specifically to assess mHealth app usability. In addition, mHealth apps offer a unique and readily accessible platform not only for the patient but also for the health care provider. To address the crucial need for evaluating the utility and usability from both patient and health care provider perspectives, the mHealth App Usability Questionnaire (MAUQ) was crafted by Zhou et al [12] in 4 different versions categorized based on the nature of the app (interactive or stand-alone) and the intended user (patient or health care provider). The MAUQ's unique design—differentiating between patient and health care provider versions and focusing on interactive app functionalities—makes it particularly suitable for evaluating how mHealth tools integrate into the complex clinical workflows of health care professionals. By focusing on dimensions such as system information arrangement and efficiency, the MAUQ provides actionable insights into clinical usability that broader quality assessment tools may not fully capture.

The necessity of a health care provider–specific version of the MAUQ is grounded in the fundamental differences between the use contexts of patients and health care professionals. While patients primarily focus on ease of use and personal health management, health care providers operate within complex clinical environments characterized by high cognitive load, time pressure, and the critical responsibility for clinical decision-making [3]. The patient version of the MAUQ, which emphasizes personal health outcomes and self-care, fails to capture these professional-specific dimensions such as the integration of mHealth tools into existing clinical workflows and the impact of app usability on patient safety [8]. Therefore, a validated health care provider–specific version is essential to evaluate whether an app facilitates clinical practice. Relying on the patient version of the MAUQ for professional users would lead to a misalignment between the tool's assessment criteria and the actual professional requirements of health care providers.

The different versions of the MAUQ have been translated into different languages and validated, such as into Chinese (interactive apps, patient version) [8], Spanish (stand-alone apps, patient version) [13], Persian (interactive apps, patient version) [14], Malay (stand-alone apps, patient version) [15], and German (stand-alone apps, patient version) [16]. However, China has not yet introduced a Chinese version of the MAUQ (MAUQ-C; interactive apps for health care providers). Therefore, the present study aimed to translate and verify the health care provider version of the MAUQ for interactive apps into Chinese.

Methods

Study Design

This was a cross-sectional study using the MAUQ. The original English version was developed to assess the usability of mHealth apps among patients and health care providers with a strong internal consistency [12]. The MAUQ for interactive apps for health care providers was used in this study. The MAUQ contains a total of 21 items and 3 dimensions: usability and satisfaction (8 items), system information arrangement (6 items), and efficiency (7 items) scored on a 7-point Likert scale ranging from 1 ("extremely strongly agree") to 7 ("extremely strongly disagree"). The usability of the app is the average score of all items (total score divided by the number of items). The closer the average score is to 1, the higher the app's usability is. A sample size of 382 participants was determined to ensure a robust participant-to-item ratio, which exceeds the minimum requirement of 10:1 for exploratory factor analysis (EFA), thereby ensuring the stability of the factor structure.

Inclusion and Exclusion Criteria

The inclusion criteria were (1) health care providers (physicians or nurses) currently working in the participating hospitals, (2) individuals who had used an mHealth app for at least 1 month to provide medical services, and (3) those who voluntarily consented to participate. Exclusion criteria were (1) individuals with less than 1 year of clinical experience and (2) those who were unable to complete the online questionnaire for technical or personal reasons.

Translation and Adaptation Process

Translation

Permission from the author of the original questionnaire was obtained through email. The translation model by Brislin [17] was adopted. The first step is forward translation, where 2 translators with native English-language proficiency independently translated the original MAUQ into Chinese versions (C1 and C2). The research team then reconciled these versions through discussion with both translators to produce a consensus Chinese draft (C3). The second step is back translation, where 2 new translators independently translated C3 back into English (E1 and E2). The research team harmonized E1 and E2 into a single English version (E3). The

XSL•FO
RenderX

third step is cross-validation, where the research team and all translators compared E3 with the original MAUQ to evaluate semantic equivalence. Discrepancies were resolved by refining C3. The revised MAUQ-C was finalized after incorporating all necessary amendments.

Experts' Comments

The expert panel consisted of 6 professionals (4 clinical health care providers, 1 software engineer, and 1 English teacher), all of whom held a master's degree or above and possessed intermediate or senior professional titles. Their expertise spanned clinical nursing, software engineering, and medical education, ensuring a comprehensive evaluation of the questionnaire's content validity. On the basis of their theoretical knowledge and practical experience, each expert evaluated the accuracy of translation, content comprehension, language expression habits, and consistency with the cultural background of each item one by one. For suggestions that were not easy to understand, the researcher had an in-depth discussion with the experts and made detailed records. Finally, the group summarized all the opinions from experts. The expert panel was selected to ensure a balance between clinical practice and technical implementation. Although the panel lacked dedicated psychometricians, the experts' deep familiarity with mHealth research and clinical nursing ensured that the items were culturally adapted and clinically relevant.

Prediction Test

A preliminary survey was conducted among 10 health care providers at a tertiary hospital using convenience sampling. The survey aimed to assess respondents' understanding of the questionnaire and their perceptions of its items. Feedback and suggestions from participants were documented, and the final MAUQ-C for interactive apps was developed by integrating experts' recommendations and respondents' suggestions.

Research Objects and Tools

This cross-sectional descriptive study was conducted in 1 third-class hospital. The convenience sampling method was adopted to select health care providers from a hospital who used an mHealth app (UHealth) to provide medical services. All participants gave informed consent and voluntarily took part in the study. UHealth is an app designed for the population with chronic diseases, providing comprehensive management such as medication reminders, online consultation, and disease knowledge [18]. The inclusion criteria were physicians or nurses who had ever used the UHealth app. The research tools included the MAUQ-C and health care workers' general information, including their age, sex, marital status, educational level, and professional title.

Verification of the Questionnaire

Item Analysis

The central tendency of the responses to each item was first examined. If a single response option accounted for over 80% of the total responses for an item, the item was considered to have weak discriminative power and was thus eliminated. Next, independent-sample 2-tailed *t* tests were conducted to compare mean scores between high- and low-score groups (top 27% vs bottom 27% of the total scores), with items showing no significant between-group differences ($P>.05$) being removed. Finally, Pearson correlation analysis was performed between individual item scores and the total questionnaire score, and items with poor correlation ($r<0.30$; $P>.05$) were excluded to ensure construct validity.

Reliability and Validity Testing

Six experts in mHealth were invited to evaluate the relevance of the questionnaire contents. A 4-point Likert scale was used to evaluate the correlation between each item (1="not related"; 4="strongly related"). The content validity index (CVI) was calculated. Principal component analysis and maximum variance orthogonal rotation were used for EFA. Items with a load factor of less than 0.40 were deleted [19]. The correlation matrix between each dimension and the total score of the questionnaire was tested, and the internal correlation analysis was carried out. Confirmatory factor analysis (CFA) was undertaken to verify whether the structure of the questionnaire was consistent with the theoretical structure of the original questionnaire. The reliability of the questionnaire was evaluated using the Cronbach α coefficient, test-retest reliability, and split-half reliability.

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and was approved by the ethics committee of Changhai Hospital (approval CHE2023-061). All participants provided informed consent before taking part in the study. On the first page of the online survey, we provided a detailed introduction to the study and an informed consent form. Participants were required to click a box stating, "I agree to participate in this research of my own volition" to proceed. The Wenjuanxing platform automatically logged their consent, and participants were free to opt out at any time by closing the survey. To ensure privacy and confidentiality, all collected data were deidentified and stored in a secure, password-protected database accessible only to the research team. No personally identifiable information was collected or disclosed, and no compensation was provided.

Results

General Information

A total of 382 questionnaires were forwarded to health care workers in the hospital who used an mHealth app to provide medical care services for patients. Of these 382 health care workers, 248 (64.9%) were male, and 134 (35.1%) were female. Most users (n=363, 95%) were under 50 years of age. Table 1 provides further details.

XSL•FO
RenderX

Table 1. General characteristics of the study participants (N=382).

Category and classification	Participants, n (%)
Sex	
Male	248 (64.9)
Female	134 (35.1)
Age (y)	
<30	92 (24.1)
30-40	184 (48.2)
40-50	87 (22.8)
≥50	19 (5)
Length of service (y)	
≤5	114 (29.8)
5-10	145 (38)
10-15	68 (17.8)
≥15	55 (14.4)
Professional rank and title	
Junior	53 (13.9)
Intermediate	208 (54.5)
Senior	121 (31.7)

Item Analysis

The results (Table 2) indicated a significant difference between the high- and low-score groups (t_{211}=−14.497; *P*<.001). Items with no statistically significant difference (critical ratio<3 or *P*<.05) between the high- and low-score groups would be deleted [20]. However, the results showed that there were significant differences (critical ratio=8.594-16.613; *P*<.001) in each item between the high- and low-score groups; thus, no item was deleted.

The Pearson correlation coefficient was used to assess the correlation among 21 items. Items with a correlation coefficient below 0.4 or a *P* value below .05 would be deleted. As shown in Table 3, all the items were significant, and a positive correlation was found among the values of the assessment phase. The correlation coefficient between the score of each item and the total score of the questionnaire was calculated (0.505-0.743; *P*<.001); thus, all items were retained.

Validity Testing of the Questionnaire

As shown in Table 4, the score range of the CVI in the questionnaire was 0.833 to 1 (minimum value≥0.78) [20], indicating that the items were comprehensible, and the CVI of the total score of the questionnaire was 0.992.

Structural Validity

Exploratory Factor Analysis

The validity of the questionnaire was assessed through EFA of the values of the Kaiser-Meyer-Olkin (KMO) test, the Bartlett test of sphericity, common degree (common factor variance), load factor, and other indicators. The KMO test was conducted before factor analysis to evaluate whether the data were suitable for EFA. The KMO value of this study was 0.932 (>0.900), which indicated that the questionnaire had an acceptable validity. At the same time, the Bartlett test of sphericity was carried out to determine whether the correlation coefficient between items was significant. The value of the Bartlett test was $P<.001$, indicating that the questionnaire data were very suitable for EFA. According to the maximum variance method, the factors with eigenvalues greater than 1 were extracted from the 21 items, resulting in the extraction of 3 common factors with eigenvalues greater than 1. The cumulative contribution rate of these 3 common factors was 63.48% (>60%), indicating that the scale structure was more consistent with the theoretical structure. Detailed results are shown in Table 5.

The orthogonal rotation method was used to analyze the crushed stone diagram (Figure 1). The dimensions of each item were the same as those in the original version and, ultimately, resulted in an MAUQ-C for health care providers with 21 items including 3 dimensions: usability and satisfaction (8 items), system information arrangement (6 items), and usefulness (7 items).

The results of EFA are shown in Table 6.

[a]The italicized items have a sufficiently strong and meaningful association with their assigned latent factors in the measurement model.

Confirmatory Factor Analysis

As shown in Figure 2, in this model, the minimum discrepancy/df value was 1.810; the root-mean-square error of approximation was 0.058; the incremental fit index and cumulative fit index values were both 0.950; the goodness-of-fit index, normed fit index, and relative fit index values were 0.887, 0.895, and 0.881, respectively; and the parsimony normed fit index value was 0.793. All the goodness-of-fit indexes met the general standard, which proves that the fitness of the model was good.

XSL•FO
RenderX

Figure 2. The confirmatory factor analysis model for the Chinese version of the mHealth App Usability Questionnaire. e: error, residual; F: factor.

Reliability Testing of the Questionnaire

The Cronbach α coefficient of the MAUQ-C was 0.919. A higher α value suggests greater internal reliability, and more than 0.700 is acceptable as good internal reliability. The values for test-retest reliability and split-half reliability were 0.881 and 0.726, respectively. The reliability of each dimension of the questionnaire is shown in Table 7.

Table 7. Questionnaire reliability analysis results.

	Cronbach α	Test-retest reliability	Split-half reliability
Dimension 1	0.928	0.759	0.933
Dimension 2	0.877	0.874	0.875
Dimension 3	0.886	0.745	0.903
Overall questionnaire	0.919	0.881	0.726

Discussion

Principal Findings

mHealth apps that provide health information and comprehensive management may be helpful both for patients and health care workers, and their use should be encouraged. The evaluations of health care providers as the main users of mHealth apps are also critical. Thus, we translated the original MAUQ (interactive apps for health care providers) into Chinese and validated the modified questionnaire in our study. This study represents the first cross-cultural adaptation and validation of the MAUQ for interactive apps for health care providers into Chinese, addressing a critical gap in usability assessment tools for medical professionals in China's mHealth landscape.

The Chinese adaptation process of the health care provider version of the MAUQ was standardized. Before the Chinese adaptation of this scale, authorization was obtained, and the preparatory work was standardized. The translation model by Brislin [17] was strictly followed. The translators and back translators all had a master's degree or above. For the disputed items in each version, decisions on modification were made through collective discussions by the research group, so the translation process was standardized and accurate. After the initial Chinese-adapted scale was developed, experts in the fields of medicine and English were invited to conduct cross-cultural adjustments from different professional perspectives. Revisions were made while ensuring the equivalence of the Chinese-adapted scale and the original scale to the greatest extent so as to ensure accuracy, comprehensibility of the item content, and its consistency with the local culture and further improve the adaptability of the scale. Then, a preliminary validation was carried out among medical staff. Methods such as item analysis and reliability and validity tests were used to test the internal consistency and effectiveness. The results of the presurvey study showed that the items of this Chinese-adapted scale were clear, which was convenient for the research participants to understand and answer. Therefore, the Chinese adaptation process of this scale was scientific and standardized, and the results were reliable.

Reliability evaluation can reflect the stability and consistency of the scale. In this study, the Cronbach α was used for consistency testing, and test-retest reliability was used for stability testing. The results showed that the Cronbach α of the MAUQ-C for health care providers was 0.919 (>0.8). The Cronbach α values of the 3 dimensions of the scale were 0.928, 0.877, and 0.886, all above 0.8, indicating that the Chinese-adapted scale had good internal consistency. The overall test-retest reliability of the scale was 0.881, and the test-retest reliability of each dimension was 0.759, 0.874, and 0.745, all above 0.7, indicating that this Chinese-adapted scale had good stability. Validity evaluation can show whether the scale truly and accurately reflects the content it surveys. In this study, methods such as content validity and factor analysis were used to test the validity of the Chinese-adapted scale. The content validity results showed that the I-CVI (0.833-1) of each item and the Scale-Content Validity Index/Average (0.992) of the scale met the standards, indicating that the experts had a high degree of recognition of the Chinese-adapted items and their corresponding measurement content and each item could effectively reflect the usability of the procedure, which indicated that the content validity of the MAUQ-C for health care providers was good. EFA extracted 3 common factors, which were consistent with the dimension division of the original scale, indicating that the item results were reasonable and the structural validity was good. The CFA results showed that the model fit met the standards (minimum discrepancy/df=1.810; root-mean-square error of approximation=0.058; incremental fit index=0.950; comparative fit index=0.950; goodness-of-fit index=0.887; normed fit index=0.895; relative fit index=0.881), indicating that the Chinese-adapted scale was consistent with the original scale in structure. These psychometric properties are consistent with previous validation studies of the MAUQ in other languages [8,11,15]. For instance, the 3-factor structure identified in our study aligns with the original development study by Zhou et al [12], confirming that the usability dimensions—usability and satisfaction, system information arrangement, and efficiency—are robust across different cultural and linguistic contexts. This cross-cultural stability suggests that the MAUQ-C is a reliable instrument for measuring usability among Chinese health care providers, offering a solid foundation for further research in this population.

Owing to the rapid development of the internet, mHealth apps have also developed rapidly. As the usability evaluation of apps can effectively identify and correct problems in and thereby optimize their operation, this method has become a common step in the app development process. In addition, the usability of apps also affects patients' use experience and the final intervention effect. Therefore, scholars at home and abroad have paid more and more attention to the usability evaluation of mHealth apps in recent years [10]. Unlike widely used instruments such as the SUS, Software Usability Measurement Inventory, or Questionnaire for User Interaction Satisfaction—which focus on technical usability for general software or websites—the MAUQ is uniquely tailored to mHealth contexts. Its differentiation between patient and health care provider versions and emphasis on interactive app functionalities addresses the specialized needs of health care professionals, whose perspectives are critical for optimizing the clinical workflow integration of mHealth tools.

The robust psychometric properties of the MAUQ-C suggest that usability is not a monolithic construct but is highly context dependent. Unlike general usability scales (eg, the SUS), the MAUQ-C's focus on system information arrangement and efficiency reflects the specific cognitive and operational demands placed on health care providers. The mechanism underlying this validity lies in the instrument's alignment with the clinical workflow; when an app reduces the cognitive load of data entry or information retrieval, app users perceive higher usability. This study's original contribution is that, first, it provides a psychometrically sound instrument tailored to the Chinese clinical environment and, second, it shifts the focus of mHealth evaluation from generic technical performance to professional-specific utility, which is a prerequisite for the successful integration of digital health into routine clinical practice.

XSL•FO
RenderX

Debates in mHealth usability research have highlighted the tension between subjective self-reported measures and objective behavioral metrics. While objective data (eg, task completion time and error rates) provide precise insights into technical performance, they often fail to capture the user's cognitive load, satisfaction, and perceived workflow integration—dimensions that are critical for long-term app adoption in clinical settings. Our study contributes to this debate by demonstrating that the MAUQ-C provides a reliable subjective assessment that complements rather than replaces objective performance data. However, we acknowledge that relying solely on self-reported instruments may be subject to recall and social desirability bias. Future research should aim to triangulate MAUQ-C scores with objective use logs to provide a more holistic view of mHealth usability.

Unlike previous system usability evaluation tools, the MAUQ was not only developed for mHealth apps. Its 4 original versions are also carefully divided according to whether the app interacts with patients, and the evaluation objects are divided into 2 categories: patients and medical staff, which is more targeted. While the patient version of the MAUQ has been adapted into Chinese, this study fills the unmet need for a validated health care worker–specific tool. This is significant because health care providers serve as both end users and intermediaries in mHealth interventions, making their usability feedback essential for enhancing app adoption and effectiveness in clinical settings.

Limitations

This study has several limitations. First, the evaluation was restricted to an app for populations with chronic diseases; future research should validate the MAUQ-C across diverse mHealth contexts to ensure broader generalizability. Second, the use of convenience sampling in 2 hospitals may introduce selection bias; thus, multicenter randomized studies are recommended to enhance representativeness. Third, the cross-sectional design precludes the assessment of long-term usability or the impact of app updates; longitudinal studies are needed to capture evolving user perceptions. In addition, conducting EFA and CFA on the same dataset may have inflated model fit indexes. Future validation should use a split-sample approach or independent datasets to provide a more rigorous confirmation of the factor structure. Finally, this study lacks an assessment of convergent and discriminant validity. Future research should compare the MAUQ-C with established usability instruments such as the SUS or the PSSUQ to further demonstrate its unique utility and construct validity in measuring mHealth usability for health care professionals.

Conclusions

The MAUQ-C for interactive apps for health care providers is a psychometrically sound and culturally adapted tool ideal for assessing mHealth app usability in Chinese clinical settings. Its validation advances mHealth research and practice by providing health care professionals, developers, and researchers with a reliable instrument to drive user-centered design and improve the quality of digital health interventions.

Acknowledgments

The authors sincerely thank Dr Leming Zhou for kindly granting permission to translate the mHealth App Usability Questionnaire into Chinese. They also extend their gratitude to all experts who provided valuable insights during the translation and cultural adaptation process. Finally, the authors would like to express their appreciation to the participants for their time and contribution to this study. Generative AI was used for language polishing and grammar correction.

Abstract

Background: On a population level, mental health apps are accessible and effective. However, nondigitally native adults with chronic pain are a large and growing population who have been neglected during the development process of these interventions. Although technology use is rapidly growing among this population, their engagement with mobile health–related apps is lagging because usability is often not optimized for their needs and preferences.

Objective: This study aimed to identify design preferences and determinants of engagement with mental health apps by nondigitally native adults who have chronic pain and coexisting symptoms of depression or anxiety.

Methods: In this qualitative study, participants completed a semistructured interview regarding their experience with, and perceptions of, mobile devices, apps, and digital health interventions. Participants were 45 years or older; scored ≥10 on the 9-item Patient Health Questionnaire, 7-item Generalized Anxiety Disorder, or both; endorsed pain on most days or every day in the past 3 months; and were living in the United States. The interview guide was informed by the Consolidated Framework for Implementation Research and the Behavioral Intervention Technology model. Codes were organized into themes. Recruitment continued until thematic saturation was achieved.

Results: A total of 42 participants were interviewed (mean age 57, SD 8 years; n=32, 76% women). Participants strongly preferred apps that are free, describe strong privacy policies, and add functional value to their lives. They were more motivated by “real-life” goal achievement and tangible health improvements than by gamification within an app, and many were wary of allowing apps to passively collect certain types of data, especially to make inferences about their mental health. Most participants were unaware of apps designed to address chronic pain, but they were interested in the concept, particularly to help track their mood and pain and then identify associations between their symptoms, app activity, and other life events. Despite their daily use of apps, many participants described frequent challenges related to app navigation. While on-demand access to app tools was preferred, most participants appreciated the potential value of occasional push notifications if their timing was thoughtful and customizable. Participants cautioned against an overly cheerful, “infantile,” or informal tone for an app that addresses serious issues such as mental health and chronic pain.

Conclusions: Mental health apps for nondigitally native adults should highlight tangible health improvements that can be achieved from app engagement (more so than gamification), potentially using a multidomain tracking feature, if appropriate. This population is available to receive just-in-time adaptive interventions, but the frequency and timing should be thoughtful, customizable, and not wholly reliant on passively collected personal data. Health-related apps designed to address conditions that are more common with increasing age should account for these preferences.

KEYWORDS

anxiety; chronic pain; depression; digital health; digital mental health intervention; engagement; mHealth; middle-age; mobile app; navigation; older adult; usability; user-centered design

Introduction

Chronic pain commonly coexists with depression and anxiety, and the prevalence of chronic pain increases with age. In the United States, nearly one-third of middle-aged and older adults are living with chronic pain, and up to half of them have depression, anxiety, or both [1-4]. Furthermore, chronic pain reduces the effectiveness of stand-alone mental health treatment unless a person's pain is simultaneously addressed [5,6]. Regardless of the etiology, chronic pain is associated with increased rates of recurrent depressive and anxiety episodes, reduced rates of remission, and reduced efficacy of antidepressant medications [7-10]. For these patients, addressing their mental health and pain experience simultaneously is more effective than addressing either problem in isolation [11].

Additionally, technology use is rapidly growing in these age groups, but engagement with digital health interventions is lagging because usability is often not optimized for their needs and preferences [2,7-10,12-23]. At this time, the majority of middle-aged and older adults are nondigital natives, meaning they were born before 1980 and grew up before immediate access to technology was widespread [24,25]. Compared to younger (and digitally native) users, this population more often has a greater interest in interventions that address multimorbidity; they prefer different screen layouts due to age-related changes in visual acuity, eye tracking patterns, and dexterity (eg, simple and flat navigation structure, large labeled buttons, and minimal need for typing); and they may benefit from more "push" notifications because they check their mobile devices less frequently. Some also have age-related cognitive deficits that reduce their ability to navigate through apps [20,26-31]. Although these age-related preference differences are now well-established, the user design of commercially available digital health apps has often continued to lag behind accepted design recommendations [32].

On a population level, digital mental health interventions, including mobile apps, effectively reduce depression and anxiety symptoms, and they have produced clinical outcomes that are equivalent to face-to-face treatment [17,19,33,34]. They also improve access to mental health support by reducing common barriers due to stigma, transportation, cost, and provider shortages that too often limit access to trained mental health professionals [35,36]. In recent years, the increasing availability of artificial intelligence has only accelerated public interest in using technology to address mental health symptoms [37-41]. Nevertheless, some populations have been neglected during the development process of mental health apps [42], and nondigitally native adults with chronic pain are one such understudied, yet growing and significant population [20].

The purpose of this study was to narrow this evidence gap by exploring design preferences of nondigitally native adults who have chronic pain and coexisting symptoms of depression or anxiety, with particular emphasis on examining determinants of engagement with mental health apps. This study is the first phase of a 3-phase project using the Discover, Design/Build, and Test (DDBT) framework to design and launch a mental health app that is optimized for the usability needs and design preferences of this population [43,44].

Methods

Study Design

In this formative qualitative study, each participant completed a single semistructured interview regarding their first-hand experience with, and perceptions of, mobile devices, apps, and digital health interventions [45,46]. Participant interviews occurred between April 3, 2024, and October 2, 2024. Data analysis occurred in 2024 and 2025. The study details are described in accordance with the Consolidated Criteria for Reporting Qualitative Research (COREQ) guidelines [47]. Of note, study participants also completed usability testing of a mental health app and provided feedback on specific usability-related features as part of the 3-phase project. These findings are reported separately [48].

Ethical Considerations

Prior to participant recruitment, approval of the study and all related procedures was obtained from the Washington University Institutional Review Board (IRB; 202311024). Participant consent was obtained via a waiver of written informed consent, and participants' data were maintained in secure databases and were deidentified before sharing with anyone outside the IRB-approved study team. Participants received a US $30 gift card as remuneration for participation.

Participants

To be eligible, potential participants had to be at least 45 years of age, report at least moderate depression or anxiety symptoms (9-item Patient Health Questionnaire [PHQ-9] score of ≥10, 7-item Generalized Anxiety Disorder [GAD-7] score of ≥10, or both), and endorse chronic pain (defined as pain on most days or every day in the past 3 months) [2,49,50]. Potential participants were excluded if they endorsed an active mental health crisis that warranted escalation of care (eg, active suicidal ideation and psychosis), had cognitive impairment that would interfere with communication with the interviewer, or lived outside the United States.

Recruitment

Potential participants were recruited from a variety of sources including from a chronic musculoskeletal pain clinic at an academic medical center (ie, printed flyers in clinic, phone call or email from the research team), email and social media advertisement via a university-based volunteer research

XSL•FO
RenderX

participant registry (ie, Facebook and Twitter/X), and targeted advertisement in the electronic newsletter of a free online health community (The Mighty). Initial eligibility screening was performed using a self-reported questionnaire hosted by REDCap (Vanderbilt University), followed by final verification by a study team member [51,52]. Recruitment and interviews continued until thematic saturation had been achieved.

Guiding Frameworks

Development of the interview guide was informed by the CFIR (Consolidated Framework for Implementation Research) and the Behavioral Intervention Technology (BIT) model [53,54]. The CFIR was used to ensure that all domains that could impact users' engagement with a mental health app were systematically addressed (ie, characteristics of the app user [individual], the user's home environment [inner setting], the user's social and structural support environment [outer setting], the user's preferred design features of the app [adaptable periphery], the app's therapeutic content [intervention], and the process of identifying, downloading, and onboarding to a new app [implementation process]) [53]. The BIT model was used to ensure that participants were prompted to comment on how an app's tools [elements], user design [characteristics], and intended timing of interactions [workflow] may impact their engagement with the app's behavioral interventions [54].

Interview Process

Semistructured interviews were conducted and recorded using audio/visual conferencing via a secure Zoom platform, each lasting approximately 45 to 60 minutes. The virtual interview format facilitated more accessible participation for people with mobility limitations related to pain, other medical conditions, transportation barriers, or geographic distance from the study site. Participants were also asked to answer sociodemographic descriptive questions via an electronic REDCap questionnaire, either before or after completing the interview. During the interviews, only the interviewer and participant were present. The interviewer described the rationale and purpose of the study, and then participants were asked questions from the interview guide (Multimedia Appendix 1).

Analysis

Audio recordings of the interviews were professionally transcribed [55], cleaned, and chunked. A preliminary codebook was developed by the senior investigator using a deductive approach guided by the CFIR and BIT models (ALC). The codebook and coding tree were refined using an inductive approach as 3 research team members coded 5 transcripts together (ALC, AM, and CYG). At that time, >90% consensus was reached, and there were fewer than 5 discrepancies between coders. After these discrepancies were discussed and resolved through consensus, the codebook was refined accordingly, and the rest of the transcripts were each coded by a single team member (AM or CYG) using NVivo 15 (Lumivero). Periodic coding cross-checks were performed across team members to ensure consistency. Next, we used thematic analysis to capture patterns in the data by examining relationships between codes [56]. Codes were organized into themes by a primary and secondary research team member. Participant recruitment, data collection via interviews, and data analysis were iterative and continued until thematic saturation was reached [56]. This was defined as the point at which no new themes or insights emerged from analysis of the last 3 interviews or related transcripts. Finalization of the thematic analysis was performed as a group discussion among 3 research team members (AM, CYG, and ALC), using the BIT model as a framework for organization. To optimally facilitate rapid intervention development and refinement as part of our 3-phase project, we aimed to identify and highlight both overarching themes and specific feature preferences among this population that could be implemented and iteratively tested using the DDBT framework.

Reflexivity, Rigor, and Reproducibility

The senior investigator was a female physician scientist with a clinical background in physiatry and musculoskeletal medicine (ALC). The interviews were conducted by a senior female research coordinator who has clinical research experience working with older adults and in the field of mental health (AM). The interviewer was not involved in clinical care, and participants' only contact with the interviewer was related to study recruitment, consent, and participation. The third member of the coding and analysis team was a female physiatry resident trainee (CYG). Additionally, a clinician scientist with mental health clinical expertise (SMH) and a health IT expert (JA) were involved in finalizing the study design, interview guide, and interpretation of themes. Although formal member checking was not possible due to the single-session nature of participant involvement, informal member checking was performed by the interviewer by paraphrasing participants' statements during interviews to ensure the participants' thoughts and opinions were correctly understood. Additionally, preliminary themes from early interviews were iteratively shared with later participants, who generally affirmed their face validity.

Results

Overview

Of 62 people who completed the screening questionnaire and were determined to be eligible, 42 participants who represented a range of sociodemographic backgrounds were invited and participated in the study, at which point thematic saturation had been achieved (mean age 57, SD 8 years; n=32, 76% women; at least n=28, 67% non-Hispanic White; n=40, 96% used the internet at least multiple times a day; Table 1). We identified themes that cut across the CFIR domains and related to factors that impact participants' general use of mobile devices and apps, in addition to determinants of engagement with health-related apps and specifically mental health apps.

Table 1. Participant characteristics (N=42).

Characteristic	Value
Age (years), median (IQR; range)	55 (51-61; 45-76)
Sex[a], n (%)	
Female	32 (76)
Male	10 (24)
Race, n (%)	
White	30 (71)
Black or African American	9 (21)
Other	1 (2)
More than one race	1 (2)
Prefer not to answer	1 (2)
Ethnicity, n (%)	
Hispanic or Latino	3 (7)
Not Hispanic or Latino	36 (86)
Unknown or prefer not to answer	3 (7)
Employment status, n (%)	
Disabled	13 (31)
Working full-time	11 (26)
Retired	10 (24)
Working part-time	4 (10)
Unemployed	2 (5)
Prefer not to answer	2 (5)
Frequency of internet use[b], n (%)	
Most of the day	12 (29)
Multiple times a day	28 (67)
At least once a day	1 (2)
Less than once a day	1 (2)
Duration of chronic pain (years), median (IQR; range)	12 (8-20; 2-65)
High-impact chronic pain present[c], n (%)	33 (80)
BPI[d] Pain Interference score, median (IQR; range)	7.1 (6-8.1; 2.4-9)
PHQ-9[e] score, median (IQR; range)	14 (12-17; 7-22)
GAD-7[f] score, median (IQR; range)	12 (9-15; 1-21)
Prior mental health treatments, n (%)	
Medication	30 (71)
Psychiatrist, psychologist, or therapist	28 (67)
Self-management (meditation, mindfulness, deep breathing, etc)	21 (50)
Support group	10 (24)
Mental health app	4 (10)
None	3 (7)

[a]Sex and gender identity were concordant for all participants.

[b]Self-reported internet use was captured by the Pew Digital Savviness Classifier [57].

[c]"High impact chronic pain" is defined as pain that limits life or work activities on most or every day over the past 3 months [2].

XSL•FO
RenderX

[d]The Brief Pain Inventory (BPI) Pain Interference score ranges from 0 to 10 [58]. Higher scores indicate greater pain interference.

[e]The 9-item Patient Health Questionnaire (PHQ-9) is a 9-item screening measure for depressive symptoms [49]. Scores range 0-27. Higher scores suggest more depressive symptoms.

[f]The 7-item Generalized Anxiety Disorder (GAD-7) is a 7-item screening measure for anxiety symptoms [50]. Scores range 0-21. Higher scores suggest more anxiety symptoms.

General Use of Mobile Devices and Apps

Users Are Constantly Connected

Our nondigitally native adult participants reported having their mobile devices within arm's reach essentially during all waking hours, largely out of necessity for daily life activities such as finances and urgent communication, as well as for leisure especially related to social connection (Table 2). Most participants reported typically responding to mobile device messages immediately or at least within the same day.

XSL•FO
RenderX

Table 2. General patterns of mobile device and app use among nondigitally native adults who have chronic pain and coexisting symptoms of depression or anxiety.

Theme	Representative quote
Tools	
Life navigation: participants typically used apps "because they have to" *for daily life* (eg, for driving directions, banking, taxes, shopping, coupons, alarm clocks, current events, and having a contact method in case of emergencies).	• "I pretty much use my phone for absolutely every aspect of my life...work, grocery list, like everything." (48-year-old male)
Leisure: participants also frequently used apps that facilitate *social connection and entertainment* (eg, social media, video chatting, taking pictures, shopping, and, less commonly, to play games).	• "Keep in touch with other people, movies and TV, sometimes books, sometimes for my grandkids." (60-year-old female)
User design	
Usability challenges with mobile devices: participants commonly experienced challenges using their mobile devices due to *dexterity difficulty* with their screen's size and *forgetting passwords*.	• "Remembering my password is definitely [a challenge]. Sometimes finding the right one, because if you put in an AT&T one, sometimes there's three or four of them and it's like, 'Which one is the one that I should actually be downloading?'" (60-year-old female)
Usability challenges with apps: participants also reported challenges navigating within some apps, understanding *how to take advantage of all an app's features*, and *reducing unwanted notifications* for some apps.	• "Some of the apps are confusing with how they want you to move around, and they don't really explain it." (60-year-old female) • "Trying to figure out everything that the app does—to make sure I'm using the maximum of everything that it does." (53-year-old female) • "Some of my apps give me notifications that I don't really want. Figuring out how to turn off unwanted notifications can be a challenge." (64-year-old female)
Troubleshooting: when participants have trouble navigating an app, they typically *first "push around" on their own* to troubleshoot. Next, they search the internet for assistance. Finally, they reach out to their social circle or a professional for navigation assistance if needed.	• "Pretty much in this order—I will try it on my own. Then I will look up a video because it's like, 'I'm determined to do this.' But then if it's something too complicated, then usually I call one of my kids." (53-year-old female)
Timing of interactions	
Availability for alerts: most participants kept their smartphones *almost always within arm's reach*, except maybe silenced while sleeping or driving.	• "I rarely turn it off." (60-year-old female)
Response time: participants typically responded to mobile device messages *immediately or within the same day*.	• "[I respond] when I see them, if I need to." (50-year-old female)
General app preferences	
Pros: participants preferred apps that are *free*, *functionally meaningful*, personally relevant, and ideally have good brand reputation.	• "I don't typically pay for a lot of the apps. There's usually free versions of something out there that you can find...There is a medication that I use that they have you download the app for, and there's no point to it. There's no purpose to it, so it's just taking up space on my phone." (49-year-old female)
Cons: participants were less likely to use apps that raise *privacy concerns* about how their data will be used or that frequently display advertisements. Some participants were also less likely to use apps that require high data usage or a stable internet connection.	• "Making sure tracking and invasion of privacy is not an issue." (72-year-old male)

Preference for Free, Useful, Trusted Apps

Participants strongly preferred apps that were free. They also gravitated toward apps that were functionally meaningful, personally relevant, and well-established with a good reputation. They reported being less likely to use apps that do not provide sufficient reassurance that users' privacy and data will be protected. Many also disliked frequent advertisements within apps.

Challenges With Navigation and Notifications

Participants reported commonly experiencing usability challenges with mobile devices due to difficulty with dexterity and forgetting passwords. They also described challenges navigating some apps, particularly with regard to understanding how to use all of an app's features and reducing unwanted notifications from apps. When usability challenges are encountered, participants most frequently reported troubleshooting by "pushing around" on their own, followed

XSL•FO
RenderX

by searching the internet for assistance (eg, Google and YouTube), and then reaching out to their social circle or professional assistance as a last resort.

Determinants of Engagement With Health-Related Apps: Interest in Content and Tracking Capabilities That Result in "Real-Life" Goal Achievement

Participants most frequently reported using health-related apps for education (eg, to learn new information), accountability (eg, for assigned tasks and reminders), and community (eg, to connect with people who are living with similar challenges; Table 3). Tracking capability was a common theme among desired functions of health-related apps, whether to track physical activity, biometrics, mood, food intake, or another health-related measure. Nevertheless, participants insisted on clear communication and ability to choose which types of passive data are collected and for what purposes, due to concerns related to privacy and "creepiness" (eg, acceptable to passively collect step count but not location). Most participants also did not consider gamification with rewards within a health-related app to be a meaningful motivator of behavior change or engagement. However, participants did report being more likely to value and use a health-related app if it is recommended or hosted by a medical professional. Regarding the timing of app interaction, participants highly appreciated the capability to customize the time and frequency of push notifications and other prompts from the app.

XSL•FO
RenderX

Table 3. Determinants of engagement with health-related apps among nondigitally native adults who have chronic pain and coexisting symptoms of depression or anxiety.

Theme	Representative quote
Tools	
Goals: participants used health-related apps for *education, accountability, and community*.	• "I primarily enjoy getting information from them." (61-year-old female) • "I've done [a fitness app]...and [a mental health app]. I know what I need to do each day, and I don't have to worry about remembering it. So I can log in, and each day I know I need to tackle these kind of tasks." (49-year-old female) • "I use [an online health community app]. A lot of people have the same experiences I do. So that's why I like it. The same thing that I go through—people not believing me—it gives you a lot of insights." (51-year-old female)
Function: in descending order, participants most commonly used apps for activity/fitness tracking; blood sugar, blood pressure, and weight tracking; mental health, mindfulness, and mood tracking; food/calorie tracking; medication refills and communication with a health care provider; and sleep assistance.	• "I have a [fitness tracking] app for monitoring my steps and water. My oncologist, once I was finished with treatment, wanted me to make sure I walked 10 to 15,000 steps a day." (60-year-old female)
Tracking: participants predominantly used health-related apps to assist with tracking one or more elements of their health.	• "The step counter is really probably the only one I use regularly." (50-year-old female)
User design	
Selective enthusiasm for passive data: the majority of participants were *open to passive collection of some types of data but not others* due to privacy concerns. If an app does passively collect data, they strongly voiced a need for the app to clearly describe the purpose and extent upfront, with an option to opt out.	• "I tend to steer away from apps that ask me that kind of information because I'm not comfortable being tracked in where I am, what I'm doing. I just find it intrusive. I mean, I put my weight on there, my height, it has my blood pressure and my heartrate—so that's pretty personal, but location—I do not share... [Passive data tracking] is a little creepy." (66-year-old female) • "I want to be able to pick when I use [passive data]. I don't want it to be able to use it and pick me. I mean, I need reminders to use [the app], but not by my location." (62-year-old female)
Low enthusiasm for gamification: most participants *did not consider embedded games or rewards as a meaningful motivator* to engage with a health-related app.	• "I don't know if I'm a typical guy or maybe not, but I don't like games. When it comes to something like this, I'm not motivated by a reward. I would rather see [all my tool] options than, 'Good boy, good boy.' ...When it comes to counting my steps, it is nice at the end of the night to have hit my target or beyond. So in that sense, yes, an emotional reward is a good thing. But the reward is that I've accomplished what I want. I don't need something extra on top of that." (72-year-old male)
Timing of interactions	
Participants strongly preferred the ability to *customize their timing of interaction* with the app (eg, time and frequency of push notifications and ability to turn off push notifications).	• "I like if it allows you to set what time you want [for check-ins]." (64-year-old female) • "I would like the option [of changing the check in frequency]." (55-year-old female)
General app preferences	
Source: participants were more likely to use a health-related app if it is *recommended by a medical professional* or directly offered from their medical provider/hospital system.	• "It's normally based on advice from a medical professional that I would download something of this type." (51-year-old male)

Determinants of Engagement With Mental Health Apps That Address Chronic Pain

Explanation of How "An App Can Help With Pain"

Many participants were unaware of apps that were designed to address chronic pain (in addition to mental health), nor did they understand how an app could address chronic pain (Table 4). When it was explained that such an app could guide users through pain coping strategies, participants were generally enthusiastic and expected that such an app would be helpful. Given the relative unawareness, participants expected that early in the onboarding and orientation process, such an app would provide education on the neuroscience of chronic pain and how it could help them manage and cope with chronic pain. They also expressed interest in tools related to mindfulness, cognitive behavioral strategies to improve pain acceptance, and gentle physical exercise. They generally preferred the app to guide them through a structured curriculum initially, but also to allow for self-guided exploration of app tools, if desired.

XSL•FO
RenderX

Table 4. Preferred features of a mental health app that addresses chronic pain among nondigitally native adults.

Theme	Representative quote
Tools	
Features	
• Participants were interested in having access to a variety of tools including education about chronic pain neuroscience, mindfulness exercises to help manage pain, strategies to improve pain coping and acceptance, pain and mood tracking capabilities, and gentle physical exercise. They appreciated immediate, 24/7 access to management tools.	• "I think it's probably going to be some kind of a help [to have a] mindfulness activity to help control and manage pain." (56-year-old female) • "Give me a summary of how my week was...pain, mood—both depression and anxiety—which I'm sure part of my anxiety is from the pain. Yeah." (66-year-old female) • "Last night I had trouble sleeping because of my lower back, and it's progressively getting worse. I have injections next week and so on, and I'm really looking forward to them. But in the meantime—getting up in the middle of the night and just saying, 'My back hurts, maybe there's this app I can check out.' Could be interesting." (51-year-old male)
Mood tracking	
• Participants were interested in periodic, brief, self-report assessments to track their mental health over time (eg, 4 questions as opposed to 16 questions). Participants preferred self-reporting their mood, as opposed to the app using passively collected data to infer their mood (eg, with call logs, step count, and GPS data). • Participants would be more motivated to complete self-assessments if the results are used to tailor suggestions of additional tools for them. • Participants voiced mixed sentiments regarding whether they would want their health care team to see responses to their self-reported mental health assessments.	• "If it asked, 'Hey, how was your week? Did you have any kind of issues that you need to talk about?' And then if you're honest with the app, then maybe it can touch base a little bit sooner." (48-year-old male) • "[Passive data collection to infer mood] is a little creepy." (66-year-old female) • "It can be a double-edged sword. For example, if you answer incorrectly, 'Do you feel like harming yourself?' Is somebody [from your healthcare team] going to say, 'Wait a minute, there are specific laws that say we have to take action and you have to be under care now.' If it's chronic pain, that's different. But if it's mental health, there's a big stigma with it." (51-year-old male)
Other tracking feature	
• Participants were interested in a feature to track associations between their pain symptoms, mental health symptoms, physical activity and life events, and engagement/tasks completed within the app. Their goal from this complex tracking feature would be to identify what app tools and general behaviors were helpful to reduce their symptoms. Some participants would also want to show this data to their health care team.	• "Yeah, maybe my activity level is higher. Maybe my emotional level is better. I would think tracking all of those things that correlate directly to my pain level would be good...Something where you can really see the results of the app working with you or for you would be good, but I think it would feel a little disconnected without also tracking any kind of pain scale." (56-year-old female)
Methods to encourage sustained engagement	
• Participants expected they would be motivated to sustain engagement with the app if they were instructed to set goals and had pending tasks on a to-do list, if the app helped them track their tasks completed and corresponding symptom improvement, and if the app suggested new features for them to try. They were generally not in favor of using access to new features as a reward/motivator for continued engagement. • Participants were also in favor of a free trial period of paid content before deciding whether to purchase the app (or an upgrade). There was a slight preference for a content-limited trial rather than a time-limited trial (eg, 2-4 weeks).	• "Is there stuff that you could add that you're working on in the next week, or maybe things that you didn't fully complete?" (60-year-old male) • "Suggest a tool, something that's actually useful as opposed to a gold star. Yes. Yes." (53-year-old female) • "Yeah. Having a trial and then going to paid content after the trial—that would determine for me, 'How well is this working?'" (60-year-old female)
User design	
Onboarding	
• Participants requested a clear explanation regarding how the app can help with chronic pain and mental health (eg, coping and management strategies, rather than a focus on pain severity reduction).	• "I am confused, and I don't know how this is going to work. Yeah, I guess my knees and my back are preventing me from exercising. Is that what you're talking about? Mental and physical health going together?" (66-year-old female) • "I guess...intervene in letting pain take over. I think by checking in or doing mindfulness things, you could possibly alleviate chronic pain." (56-year-old female)

XSL•FO
RenderX

Theme	Representative quote
Tone	
• Some participants thought an overly cheerful, personal tone presented by a cartoon-like avatar was less suitable for older adults and felt artificial. Similarly, participants had mixed opinions on the use of emojis throughout the app experience.	• "These kinds of issues, we don't want to make light of them, and I think a [cartoon-like chatbot avatar] kind of makes it a little childish. If this was geared toward children and teens, ok. But for adults, I think it needs to have something a little more serious... I think I would be more comfortable with more of a question-and-answer screen—more like journal prompts than a text conversation." (60-year-old female) • "For me, [emojis are] very unnecessary. [They're] infantile. I mean, but I'm old. So a lot of this stuff is goofy now, that wouldn't be goofy to other people. If a kid is using it, they might like that." (69-year-old female) • "I think an emoji is like putting an expression to a sentence. So I think it's amazing." (52-year-old female)
User flow	
• Participants generally preferred for the app to initially guide them through a structured curriculum (such as for a duration of 8 weeks) but to also allow for self-guided exploration through the app, if desired.	• "It seems like once you become familiar with what it is, self-guided would definitely be preferable." (56-year-old female) • "I think eight weeks would be good because it takes a significant amount of time to change habits or incorporate new habits." (54-year-old female)
Timing of interactions	
Notifications to prompt engagement	
• Most participants preferred to initiate engagement with the app on their own, but many participants were also welcoming or at least accepting of occasional notifications to encourage engagement if relevant. • Most participants expressed that once or twice daily notifications would be acceptable, and some participants preferred an even greater frequency of notifications. For once daily notifications, evening check-ins were more often preferred to morning check-ins. • Participants voiced varied preferences regarding the option for notification frequency to be adaptive based on their engagement. Some participants were in favor of pausing notifications (eg, for 3-7 days), while others did not want a pause in notifications unless they were specifically asked first.	• "If it recognizes that you struggled, and if you're honest with the app, then maybe it can touch base a little bit sooner." (48-year-old male) • "[Check-ins twice a day] is okay with me because I don't do anything. I'm in pain, I don't work, and all I do is go back and forth to the doctors." (55-year-old female) • "Like, you could say, 'Dismiss for three days,' or however long it is. Or let's say you're going on vacation, you could set a time limit to dismiss for seven days or however long it needs to go. Give me the option to click that button, then I can go from there." (49-year-old female) • With regards to pausing notifications: "Don't forget about me now. Everybody else in the world does. And don't give up on me. I look at that as giving up on me. Don't do that. Don't leave me." (62-year-old female)
General app preferences	
Improved awareness	
• While most participants were aware of apps designed to address mental health, many participants were unaware of apps that address chronic pain. They were also unclear as to "how an app can help with pain."	• "I had no idea there were any [apps to help manage pain]. I'm wondering what [a pain app] can do because I have no clue." (61-year-old male)
Other stressors to address	
• Participants also suggested additional stressors that should be addressed by an app that aims to improve mental health and chronic pain. These stressors commonly included other health concerns, finances, and low motivation. Mobility limitations, shame, attention issues, frustration, loneliness, time pressures, and work were also suggested.	• "It could be other health challenges. You could have something related other than just pain." (53-year-old female) • "Finances play a big part of everything you do because if you don't have it, you can't do it." (55-year-old female)

Interest in Self-Reported Symptom Tracking

Participants were particularly interested in a tracking feature that would help identify associations between their pain, mental health symptoms, daily activities and events, and engagement with the app. To track mood, participants generally preferred completing periodic, brief self-assessments, rather than having the app use passively collected data, such as call logs or step count, to infer their mood, due to concerns about privacy and the accuracy of inferences. Participants reported being motivated to complete these self-assessments if the results lead to a more personalized and relevant app experience. They were somewhat

XSL•FO
RenderX

conflicted as to whether they wanted their self-reported symptoms to be shared with their health care team. While many participants anticipated added clinical value from sharing data such as a pain diary, some of these same participants (in addition to others) expressed concern regarding how mental health symptom reports may be handled by licensed health care providers. They feared that a clinician may misinterpret their symptom reports and feel obligated as a mandatory reporter to act on concern for potential imminent danger, even if none exists.

Encouraging But Mature Tone

Several participants cautioned against an overly personal or cheerful tone for an app that addresses chronic pain and mental health because it felt artificial and less suitable for their age group. Similarly, participants had mixed opinions on the use of a cartoon-like avatar or emojis throughout the app experience. Some felt they were "infantile," whereas others felt they enhanced communication. To maximize the relevance of an app that addresses chronic pain and mental health, participants suggested additional stressors that should also be acknowledged and ideally addressed, such as other health issues, financial pressures, and low motivation.

Customized Frequency of Notifications

Most participants preferred to initiate engagement with the app on their own, but many participants were also welcoming, or at least accepting, of notifications to encourage engagement if relevant. Participants typically described once- or twice-daily notifications as being most appropriate (especially evening notifications). Most participants were also open to an adaptive frequency of notifications based on their degree of engagement. However, some participants voiced concern about feeling like the app "ghosted [them] just like people do" if notifications suddenly stopped without their explicit request.

Motivated by Real-World Results

Regarding sustained engagement with an app that addresses chronic pain and mental health, participants expected to be motivated to continue engaging if they had specific goals and a to-do list within the app, especially if they could see a correlation between task completion within the app and symptom improvement. Participants were not in favor of using access to new app tools as a reward for engagement because they wanted to have access to whichever tool they thought was most relevant at the time they needed it. Instead, participants were generally open to a free trial period of app content, which may then motivate them to purchase access to additional content (or continued access to the original content).

Discussion

Principal Results

This qualitative study investigated design preferences and determinants of engagement with mental health apps by nondigitally native (middle-aged and older) adults who have chronic pain. Similar to findings across many other user populations, our participants in this population were generally avid mobile device users, and they strongly preferred to use apps that are free of charge, describe reassuring privacy policies, and add clear functional value to their lives [59]. Participants were also generally enthusiastic about health-related apps, particularly for tracking/logging purposes, and while on-demand access to app tools was clearly preferred, most participants also appreciated the potential value of occasional push notification "engagement reminders" if the notification timing was thoughtful and customizable [59]. Building on existing literature, this study also contributes some novel insights that are more unique to this nondigitally native population with chronic pain, when compared to younger users and users without chronic pain. Specifically, despite their daily use of mobile apps, many participants described frequent usability challenges, particularly related to app orientation and navigation (not just due to technical issues such as an app crashing). They were also more consistently motivated by "real-life" goal achievement and tangible health improvements than by gamification within an app, and many were wary of allowing apps to passively collect data, especially for the purpose of making inferences about their mental health. Furthermore, the majority of participants were unaware of apps designed to address chronic pain, but they showed a high level of interest in the concept. They were particularly interested in an infrastructure to track both their mood and pain symptoms and then identify associations between their symptoms, their activity on the app, and other life events. Finally, the participants cautioned against an overly cheerful, "infantile," or informal tone for an app that is intended to support adult users with serious issues related to mental health and chronic pain.

Comparison With Prior Work

The constellation of preferences that participants expressed presents a challenge when designing and delivering a health-related app that meets both their stated preferences and needs. Specifically, participants stated that they prefer not to be excessively bothered by push notifications. Yet, they also prefer to self-report their symptoms rather than have their symptoms inferred from passive data, and they describe low motivation as a common challenge in daily life—which is consistent with previous studies that have observed reduced app engagement among users with a high severity of depressive symptoms and fatigue (such as due to chronic pain) [59]. Of note, depression and fatigue are also barriers to engagement with nondigital health interventions [60].

Ultimately, we conclude that despite growing technological potential for passively collected data to infer changes in users' mental and physical health accurately [61,62], feedback from our participants suggests that at least at this time, digital health interventions for middle-aged and older adults should not rely heavily upon passively collected data. Rather, careful iteration and customization of push notification frequency, timing, and content have consistently proven to be a key strategy for optimizing engagement with digital health interventions among people across the age spectrum [63]. For this population, effective notifications may include reminders about available tools that the user previously found helpful, previews about pain neuroscience principles that could meaningfully impact the user's mindset, and/or insights into how app engagement could help address functional challenges previously reported

XSL•FO
RenderX

by the user. Adaptive timing of notification delivery based on users' demonstrated engagement patterns may also improve acceptance and engagement [64], and any use of passively collected data (beyond app engagement data) should likely be offered as an opt-in feature, rather than a default feature. Quantitative analysis of engagement patterns and symptom severity in response to varied push notification strategies is warranted.

Another challenge is that participants preferred apps that are both free of charge but are also not filled with obtrusive advertisements. This is consistent with preferences among younger age groups in which 67% of people report only using free apps and an additional 22% only use apps that cost $5 or less [65]. Third-party reimbursement of digital health interventions, either as stand-alone therapeutics or as part of a treatment bundle offered by a health system, could address these financial preferences and also add legitimacy to the intervention in the eyes of potential users.

Participants' strong interest in health-related tracking capabilities poses a unique conundrum for chronic pain-related apps, as well. While tracking metrics such as step count and sleep quality are essentially universally encouraged by health care professionals, an app that frequently prompts a user to report their pain intensity could unintentionally increase pain rumination and subsequent discomfort and impairment [66-68]. This phenomenon is supported by prior studies among different target user populations, which have simultaneously reported high popularity of pain tracking features and mixed feedback regarding the helpfulness of these features [69,70]. Accordingly, we propose that a chronic pain-related app may consider enabling the user to systematically log pain *interference* (and potentially add free-text notes about pain severity), rather than prompting the user to frequently reflect on pain intensity.

To have the greatest impact specifically for people who are struggling with chronic pain, we also need to improve awareness about the potential and availability of digital health interventions to deliver evidence-based pain management techniques such as cognitive behavioral therapy and mindfulness exercises. Based on participants' responses in this study, middle-aged and older adults may be most interested and accepting of such an intervention if it is introduced and recommended by a trusted member of their health care team. To most effectively increase awareness, these discussions could occur in primary care and orthopedic clinics, as well as mental health care settings [71]. Feasible, sustainable uptake of this workflow would likely be facilitated by use of established billing codes for behavioral health integration, digital mental health treatment, and/or remote therapeutic monitoring.

Strengths

The broad potential applicability of our findings across multiple health domains is a strength of this study. Although the therapeutic purpose and content of various health-related apps may be somewhat distinct, common themes related to target users' preferred engagement techniques and usability features exist. Some findings from this study can be used to inform optimal design of other digital mental health interventions and/or other health-related apps for nondigitally native middle-aged and older adults, not just related to chronic pain but potentially for other purposes such as medication monitoring, organ failure symptom monitoring (eg, for heart failure, kidney disease, etc), or encouragement to engage in social interaction or physical activity.

Limitations

A limitation of this study is that the study population preferentially represents middle-aged, White females from the United States who use the internet at least multiple times daily. Therefore, we may not have fully captured themes that are uniquely relevant for older adults and for adults from other geographical or sociotechnical backgrounds. Nevertheless, even though the majority of participants reported daily internet use, we still identified usability challenges and specific opportunities to tailor digital health experiences for this group. Of note, our findings represent participants' *stated* usability and engagement preferences; quantitative assessment of participants' *actual* engagement with apps that are concordant versus discordant with their stated preferences was outside the scope of this study.

Conclusions

Nondigitally native adults who are avid mobile device users still often encounter usability challenges and report design preferences that likely differ somewhat from those of younger users. To optimally meet the preferences and needs of this population, digital health interventions should emphasize tangible health improvements (more so than gamification) that can be achieved by engaging with the intervention, potentially using a multidomain tracking feature if appropriate. This population is generally available to receive real-time messages such as for just-in-time adaptive interventions, but the frequency and timing of any push notifications should still be thoughtful and customizable. This population remains wary of allowing passive data collection of their personal information. In conclusion, digital health interventions designed to address conditions that are more common with increasing age should account for these preferences.

Abstract

Background: Nationwide electronic health records (EHRs) are intended to strengthen patient empowerment and improve information continuity across health care settings. In Germany, the electronic patient record (elektronische Patientenakte [ePA]) transitioned from an opt-in to an opt-out model in 2025. Initial survey data suggest that technical complexity and access requirements may hinder engagement; yet, little is known about how users experience this access process.

Objective: This study explored users' experiences of setting up and authenticating access to insurer-provided ePA apps and examined the barriers affecting successful access.

Methods: We conducted a qualitative interview study with individuals covered by statutory health insurance. From 61 interviews conducted within the broader ePA4all project, 23 were selected because participants had attempted to access the ePA through an insurer-provided application and described at least 1 concrete action or event during setup or authentication. Semistructured telephone interviews were conducted between August and December 2025. Data were analyzed using Kuckartz's structured qualitative content analysis. The process phases were developed inductively from the material. All 23 interviews were independently coded by 2 researchers, with differences resolved through consensus. A second analytic step examined how barriers interacted and accumulated across the access pathway.

Results: The sample included 21 participants who had successfully accessed the ePA and 2 who had initiated but abandoned setup or authentication. Setup and authentication were experienced not as a single technical step but as an interdependent process comprising 5 phases: orientation, technical entry, verification, interruption, and transition to initial use. During orientation, incomplete or outdated information left requirements and procedural steps unclear. Technical entry required users to coordinate different apps, interfaces, and device requirements. Verification involved multiple credentials, identification services, and partly repeated security steps. Technical failures, administrative inconsistencies, postal procedures, and waiting periods interrupted progression and sometimes required users to repeat previously completed steps. After successful access, an unclear immediate benefit could limit the transition to initial use. Across phases, participants relied on digital competence, prior experience, persistence, and self-efficacy to navigate the process. Difficulties were also reported by participants with high affinity for technology. Barriers could accumulate across phases: insufficient orientation increased subsequent coordination work, failures produced interruptions and repeated attempts, and prolonged effort contributed to frustration or disengagement.

XSL•FO
RenderX

Conclusions: Access to the opt-out ePA through insurer-provided apps is shaped by cumulative demands rather than by isolated technical problems. Formal provision of an EHR does not ensure that users can successfully complete the access process. Implementation should prioritize clear preregistration guidance, continuity across applications and identification services, resumable procedures, actionable error messages, and accessible support. More broadly, onboarding and authentication should be treated as integral stages in the implementation of patient-facing digital health infrastructures rather than as neutral technical prerequisites.

accessibility; digital health; EHR; electronic health record; health; patient empowerment; qualitative interviews

Introduction

As part of the digital transformation within health care systems, implementation of patient-centered health technologies into treatment pathways is increasing. These developments include the global introduction of nationwide electronic health records (EHRs) aimed at empowering individuals to manage their own health and health data more competently. EHRs are intended to improve the availability of health information to patients and encourage their active participation in care processes [1], thereby contributing to improving the quality of medical care and helping health care systems meet future challenges [1]. Patient empowerment constitutes a central guiding principle of these digital health initiatives, aiming to strengthen patients' self-efficacy and confidence in managing their health and navigating interactions with health care professionals (HCPs) [1-4].

Despite these intended benefits, the acceptance and active use of national EHR systems cannot be taken for granted. Data protection, data security, and trust in the transparent handling of health data are key determinants of the acceptance or rejection of national EHR systems [5,6]. Concerns about unauthorized access and data breaches represent some of the most frequently reported barriers [7,8]. Furthermore, usability challenges, such as complex interfaces, unclear navigation, and limited perceived value or benefit, reduce individuals' motivation to use digital health records [9].

International evidence from patient portals indicates that formal availability does not automatically translate into successful enrollment and access. In a survey of patients who had not enrolled in a portal, almost two-thirds had not attempted enrollment, most commonly because of insufficient information or motivation; negative attitudes and computer-related obstacles were additional reasons [10]. A qualitative study of the US Veterans Health Administration's national patient portal further showed that its multistep enrollment pathway, including online registration, in-person identity verification, and additional activation steps, created administrative and logistical barriers for patients [11]. These findings suggest that onboarding and authentication are not merely preliminary technical tasks but implementation stages that can determine whether patient-facing digital health infrastructures are reached in practice. However, the interaction and accumulation of barriers across these stages remain insufficiently understood.

In Germany, the electronic patient record (elektronische Patientenakte [ePA]) was introduced in 2021 [12]. At that time, individuals who had statutory health insurance could decide whether they wanted to apply for and use an ePA provided by their respective health insurance fund. In January 2025, the system transitioned from an opt-in to an opt-out model [13]. Since then, an ePA has been automatically created for all individuals covered by statutory health insurance, with the aim of enabling the storage and exchange of medical documents, facilitating cross-sectoral information flow, and strengthening patients' roles within the care process [14]. Although the ePA is established automatically, its use remains voluntary. Individuals who do not wish to use the ePA may actively object to its use. Given the central role of statutory health insurance within the German health system, this regulatory change has broad practical relevance. Approximately 75 million of Germany's 83.5 million inhabitants are covered by statutory health insurance, and 93 independent statutory health insurance funds (as of January 2026) [15] operate autonomously within a common legal framework [16]. Each statutory health insurer provides its members with its own ePA application. Access to the ePA is provided through apps offered by the respective statutory health insurers. Consequently, the ePA constitutes a national infrastructure, whereas the interfaces and parts of the setup process are implemented through multiple insurer-provided apps. While functional and technical requirements are defined by law and embedded within the national telematics infrastructure [17], differences remain in interface design, user guidance, and the specific implementation of the registration process. Consequently, access to the ePA may vary depending on the respective health insurer.

Initial findings on the use of the ePA indicate that it has thus far been used only to a limited extent. In a survey conducted in 2025, a total of 1500 individuals covered by statutory health insurance were asked about their use of the ePA. Twelve percent of respondents reported having actively set up their ePA and used it at least once. In contrast, 79% were classified as passive users who had not independently accessed their ePA to date, while 7% stated that they had objected to its use [18]. Passive users were further queried about their reasons for nonuse. Eleven percent selected the following response: too complicated, inconvenient, application does not work, no/old mobile phone [18]. These findings suggest that the uptake of the ePA may, at least in part, be hindered by challenges related to access requirements and technical prerequisites. In particular, these

XSL•FO
RenderX

findings point to the importance of the initial setup and authentication process as a potential barrier to use. However, this process has so far received little systematic attention.

The setup of the ePA application is a complex process involving multiple technical and organizational requirements. In terms of actor-network theory, ePA authentication can be conceptualized as an obligatory passage point (OPP) [19]: as a necessary bottleneck, it bundles the interactions of heterogeneous actors (patient, smartphone, ID card, electronic ID [eID], application ecosystem, network connection, and backend infrastructure) and makes access to the ePA dependent on these elements being successfully aligned in a multistage sequence. A disruption in one component may therefore interrupt the entire access pathway, even when all other requirements have been met. From this perspective, authentication requires users not only to operate an application but also to coordinate technical systems, identification procedures, and organizational requirements. From this perspective, access to the ePA is not a simple technical step but a sociotechnical process that may generate barriers at different stages. Despite this conceptualization, empirical research has so far paid little attention to how users actually experience this process.

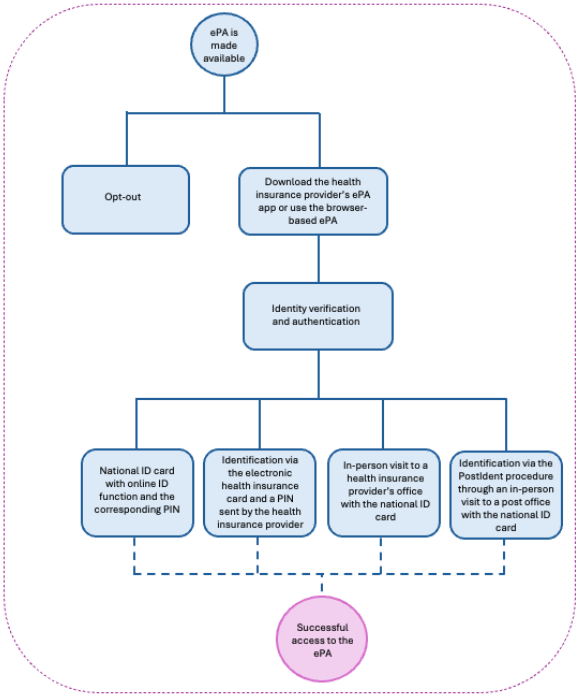
To date, there have been no studies on the subjective experiences of individuals during the ePA application setup process, mainly due to the recent introduction of the opt-out model in Germany. As a result, there is currently little insight into how users experience the registration process or at which specific stages problems may arise. Previous studies have primarily focused on the usability of digital health technologies themselves rather than on the processes of accessing or setting up these systems [8,20]. However, the effective use of the ePA presupposes that access to the ePA application is both available and manageable for users. Against this background, a deeper understanding of user experiences across the entire registration process is essential. By systematically examining challenges along this process, critical points that may hinder successful access can be identified. This study therefore explored how individuals with statutory health insurance experienced setup and authentication for their insurer-provided ePA application and which barriers affected successful access to the ePA. Initial use after authentication was considered only insofar as participants described the immediate transition from formal access to engagement with the application.

Methods

Ethical Considerations

All ethical issues were addressed. All study procedures were approved by the responsible ethics committee. All methods were performed in accordance with relevant guidelines and regulations. This study involves human participants and was approved by the Ethics Committee of the Charité Berlin (reference ID: EA1/333/24). Participants were informed verbally and in writing about the purpose, procedure, and significance of the study, as well as the associated benefits and risks, and were given the opportunity to ask questions. They were also informed that they had the right to withdraw their consent to participate in the study at any time, either verbally or in writing, without giving reasons. They were also informed that personal data would be collected and stored, whereby the data would be anonymized, but no data would be published that could be used to identify the individual. For security reasons, the data received from participants were always stored in a password-protected folder on a secure desktop computer. Written consent was obtained after participants had the opportunity to ask questions. Patients were not involved in the design of this study. Participants were offered €50 (approximately US $59.48) as an incentive for their participation in the study.

Overview



The aim of the study was to investigate how individuals with statutory health insurance experienced setup and authentication for their insurer-provided ePA application in Germany. The study focused on the process from the users' perspective, including perceived barriers and challenges from initial orientation to successful access to the ePA. Experiences after authentication were included only when they concerned the immediate transition to initial use. This study is part of the ePA4all project [21], which examines facilitators and barriers to the adoption of the ePA in Germany.

Accessing the ePA Through Insurer-Provided Applications

Active access to the ePA is primarily provided through an application offered by the individual's statutory health insurer and requires a multistep setup and authentication process. Alternatively, access via a stationary device (desktop computer) is possible if no smartphone or tablet is used. Insured individuals may grant access rights to a representative (eg, a family member). The authorized representative can view and manage the ePA on behalf of the insured person via the application. Initial access requires identity verification. Verification can be completed either via the electronic identity card in combination with a PIN or via the electronic health card in combination with a personal identification number (PIN). The PIN for the electronic health card must be requested from the health insurer. Issuance of the PIN requires prior identity verification, which can be conducted either in person at a branch office of the health insurer or through a postal identification procedure (PostIdent). In addition to the electronic health card, insured individuals may apply for a digital identity (GesundheitsID) through their health insurer. Following the application, authentication via electronic identity card or electronic health card and PIN is likewise required. After successful initial registration, simplified authentication methods may be used for subsequent logins, such as biometric procedures (eg, facial recognition), provided the device supports these functions. Available authentication options may vary depending on the device and operating system (Figure 1). The ePA is also established for children and adolescents. Until the age of 15 years, the ePA is managed by the parents or another legal guardian, who may also object to its use on behalf of the child. Upon reaching the age of 15 years, adolescents may independently manage their electronic patient record and may also exercise their own right to object [22].

Participants

Participants were recruited with the support of regional Associations of Statutory Health Insurance Physicians in Germany, including the Association of Statutory Health Insurance Physicians in Westphalia-Lippe, the Association of Statutory Health Insurance Physicians in Schleswig-Holstein, the Association of Statutory Health Insurance Physicians in Lower Saxony, and the Association of Statutory Health Insurance Physicians in Berlin. These associations contacted general practitioner (GP) practices within their respective regions and invited them to support the recruitment process. Participating GP practices received study flyers and written information materials describing the aim, procedures, and inclusion criteria of the study. The materials were made available to patients in the practices. Persons who were interested in participating were invited to contact the research team directly. Registration for study participation was possible via email or telephone. Participants were selected using purposive sampling [23]. Individuals were eligible to participate in the study if they met the following inclusion criteria:

- Legally insured under the German health insurance system
- Aged 18 years or older
- Experience as an active ePA user (defined as individuals who had successfully completed authentication and accessed the ePA through their insurer-provided application at least once) or passive ePA user (defined as individuals for whom an ePA had been created but who did not actively use the application)
- Intention to access the ePA through an insurer-provided application
- Willingness to participate in a qualitative interview

In total, 61 interviews were conducted within the broader ePA4all project [21]. All 61 interviews from the broader ePA4all dataset were screened for first-hand accounts of setup and authentication for insurer-provided ePA apps. Interviews were included if participants had personally attempted to access the ePA through an insurer-provided application and described at least 1 concrete action or event during this process. Based on this criterion, 23 interviews were selected for in-depth analysis. The remaining 38 interviews were excluded because participants had not personally attempted to access the ePA through an insurer-provided application or did not describe a concrete action or event during setup or authentication; no other exclusion reasons were applied. Of the 23 included participants, 21 were active users. The 2 passive users had initiated setup or authentication but abandoned the process before successfully accessing the ePA.

Research Team and Reflexivity

The interview team had academic backgrounds in health sciences and sociology. SM and FM had extensive experience in conducting and analyzing qualitative interviews. All interviewers had prior research experience in digital health and the German ePA, which may have sensitized them to implementation-related barriers and challenges. To reflect on the potential influence of these prior perspectives, interpretations and coding decisions were discussed within the research team and documented in analytic memos. None of the interviewers had a prior personal or clinical relationship with the participants. Transcripts and findings were not returned to participants because participant validation was not included in the study design. Instead, the transparency and dependability of the interpretation were supported through independent coding by 2 researchers and subsequent consensus discussions.

XSL•FO
RenderX

Data Collection

Data were collected through semistructured qualitative interviews. An interview guide was developed based on the study objectives and existing research on EHRs and was refined iteratively during data collection. The interview guide addressed experiences with the setup of and authentication for insurer-provided ePA apps, perceived barriers, and the immediate transition to initial use or nonuse after access (Multimedia Appendix 1). The interview guide was piloted with the first 3 participants, and no revisions were required because the questions were understood and elicited relevant accounts of setup and authentication. The interview guide therefore remained unchanged during subsequent data collection. Interviews were conducted by researchers (SM, FM, AN, MN, and FS) via telephone between August and December 2025. All interviews were conducted in German, audio-recorded with informed consent, and transcribed verbatim. Transcripts were anonymized prior to analysis. In addition, brief field notes were documented after each interview to capture contextual impressions and support interpretation of the interview situation; these notes were not included in the formal analysis. Saturation was assessed during the in-depth analysis of the 23 interviews included in the analytic subsample rather than used as a stopping criterion for data collection in the broader ePA4all study.

Data Analysis

Qualitative analysis of the interviews was performed iteratively by SM and FM based on structured qualitative content analysis by Kuckartz [24] using MAXQDA Analytics Pro 2022 (version 22.1.0; Verbi GmbH). During initial familiarization with and coding of the broader dataset, all 61 interviews were screened for relevance to the present research question. The analytic subsample was selected before the subsequent in-depth analysis of the setup and authentication process. During initial coding of the 23 included interviews, recurring topics were grouped into inductively developed main categories and subcategories. The 5 process phases were developed from the coded material and were not predefined by the structure of the interview guide. The coding system was iteratively reviewed and revised by comparing coded passages within and across interviews. Category definitions, coding rules, and illustrative examples were documented in a codebook. Analytic decisions, revisions to the category system, and points discussed during consensus meetings were documented in analytic memos. Both researchers (SM and FM) independently coded all 23 interviews using the agreed coding system. Differences in coding or category interpretation were discussed until consensus was reached. Where necessary, category definitions were clarified and the relevant material was recoded. This procedure was intended to strengthen the transparency and dependability of the analysis.

In a second analytic step, recurring patterns of access barriers across the coded material were systematically compared. Beyond phase-specific challenges, the analysis focused on the relationships between successive phases of the access process. Through iterative comparison of cases and categories, we examined how difficulties arising in one phase affected participants' progression through subsequent phases. Particular attention was paid to recurring sequences involving unclear requirements, increased coordination work, technical or administrative failure, interruption, repeated attempts, and disengagement. This second step resulted in a process-oriented interpretation of how barriers could interact and accumulate across the authentication pathway. The concept of authentication as an obligatory passage point served as a sensitizing perspective for examining how users, devices, applications, identification services, and administrative procedures had to be coordinated and how disruptions in one component affected the wider access process.

Within the analytic subsample, saturation was considered reached when the analysis of additional interviews produced no new process phases, categories, or relevant dimensions of the setup and authentication experience [25].

The data were analyzed in German. To present the findings, significant excerpts from the transcriptions were chosen as representative quotes. These quotes were translated into English and incorporated into the manuscript. The translated quotations were reviewed against the original German transcripts by bilingual members of the research team to ensure that their meaning and tone were retained. The manuscript was prepared in accordance with the COREQ (Consolidated Criteria for Reporting Qualitative Research; checklist provided in Multimedia Appendix 2) [26].

Results

Sociodemographic Characteristics

Of the 23 participants, 21 were active ePA users and 2 were passive ePA users. The 2 passive users included in the analysis had initiated setup or authentication but abandoned the process before successfully accessing the ePA. The mean age of the participants was 47.9 (SD 17.3; range 21-80) years. Most participants were male (male: n=14; female: n=9). The mean duration of the interviews was 35 (SD 8.3; range 18-50) minutes. The participants were insured with 11 different health insurance companies. Detailed characteristics of the study participants are shown in Table 1.

[a]ATI: Affinity for Technology Interaction.

[b]ATI-S: Affinity for Technology Interaction Short Scale.

The setup and authentication required to access the ePA through insurer-provided apps do not take place in a single step but unfold across several consecutive phases. Challenges rarely occur in isolation, but may interact and accumulate throughout the process. In the following, these barriers are traced along the individual process phases. Figure 2 visualizes the multistep access process of the ePA as a sequential process consisting of 5 inductively derived phases: orientation, technical entry, verification, interruption, and transition to initial use.

XSL•FO
RenderX

Figure 2. Summary of the experience of the elektronische Patientenakte (ePA) setup and usage process from the perspective of individuals with statutory health insurance.

Phase 1: Orientation

In the first phase, barriers arise even before the actual registration begins, as potential users do not perceive the process as a clearly plannable and reliable sequence of steps but rather as an uncertain endeavor with unclear requirements and insufficient guidance. The available information is experienced as inconsistent and outdated.

> *Well, there is a video, and the video seems very outdated. (...) Apparently, the health insurance company did not update it.* [ePA_13a_37_female]

The orientation gap does not only concern the timeliness of information but also the coverage of concrete use cases. This becomes particularly evident in special situations, such as setting up the ePA application for children.

> *I had no idea how I was supposed to do that [install the ePA app for my child]. I simply didn't know.* [ePA_13a_37_female]

As a result, entry into the process is not structured by a clear and comprehensible procedure but rather by an unsystematic search for relevant information, in which key courses of action remain unclear (eg, setting up the application for children or other persons). Consequently, the registration process often begins without a clear understanding of which steps are required in which order and what prerequisites need to be met.

Phase 2: Technical Entry

The phase of technical entry is characterized by structural challenges. After downloading the ePA application, entry is experienced as a fragmented sequence of different applications, procedural paths, and decision points, the underlying logic of which is only partially comprehensible to users. The need to switch between various apps, identification options, and technical interfaces generates early feelings of overload and uncertainty about the next step. This experience is described as highly burdensome.

> *At that time, I was really somewhat overwhelmed by the whole process; I experienced it as really very labor-intensive.* [ePA_12a_49_female]

The metaphor of an "authentication jungle" illustrates the perception of a confusing and difficult-to-navigate system.

> *I just got into this authentication jungle.* [ePA_1a_34_male]

Entry into the system is experienced as a process in which users have to orient themselves independently, without being actively supported by the system architecture. This fragmentation does not only concern the number of steps but also their organizational and technical distribution. Entry does not take place via an integrated platform but through a combination of the main application, identification services, and, in some cases, separate service applications.

> *Yes, this whole registration process, right, with [name of health insurance company], you have to download two apps (...) and then you also have to open a second app. (...) Especially since you can't even get into the patient record without opening the other app, so it's basically duplicated.* [ePA_7a_60_male]

As a result, a high level of coordination is required from users right from the beginning, as they must relate various technical and administrative components to one another. A lack of transparency regarding which component fulfills which function intensifies the feeling of being caught in an opaque procedure whose logic is not immediately apparent.

In addition, technical access requirements act as independent barriers that can partially prevent entry altogether. Several participants report that the process failed due to unmet device requirements or security settings.

> *And then it said, you don't have NFC on your device, you can't use this device.* [ePA_2p_80_male]

Such requirements often appear unexpectedly and are usually neither transparently communicated in advance nor easily resolved in the short term, especially when they concern hardware-related or security-relevant settings. Access to the ePA thus depends on the availability of suitable end devices. Participants whose devices did not meet these requirements were unable to proceed with the access process using those devices.

XSL•FO
RenderX

At the same time, some participants report a smooth entry when technical requirements are met and prior experience is available. In these cases, entry is perceived as uncomplicated.

> *Well, everything went smoothly.* [ePA_3a_36_female]

However, these positive experiences are limited to specific constellations and do not represent a systematic characteristic of the procedure.

Phase 3: Verification

Identity verification is not experienced as a single, clearly delineated step but as a complex sequence of multiple, partly redundant security measures, the internal logic of which is only partially comprehensible to users. Over the course of the process, various identification tools, passwords, PINs, one-time codes, and external verification services have to be coordinated. The parallel use of different security mechanisms increases cognitive load and leads to frustration.

> *And overall, there was this constant verification and logging in. And all these codes you get by email. It's just a lot.* [ePA_9a_35_male]

At the same time, uncertainty arises as to whether the current step has been completed correctly and whether it will result in sustainable progress within the process. Identification is thus not experienced as a stable transition point but as a fragile intermediate state that can collapse at any time.

> *I felt like in the story of the hare and the hedgehog. You're constantly being sent back and forth.* [ePA_2p_80_male]

This fragility becomes particularly evident in the frequently reported technical breakdowns during verification. Several participants describe that redirects to external identification services or internal verification modules do not function reliably.

> *Then, in that verification process, the page just didn't load.* [ePA_9a_35_male]

In other cases, the process breaks down completely.

> *The process technically crashed for me, and then I basically had to do it several times.* [ePA_17a_32_male]

Such breakdowns not only terminate the current step but often lead to previously completed verification stages losing their validity. Users are therefore forced to repeat the entire identification process, regardless of how far they had already progressed. The associated uncertainty increases emotional pressure, as each additional attempt is accompanied by the expectation of renewed failure.

In addition to technical disruptions, administrative challenges also act as independent barriers in this phase, for example, due to inconsistencies in personal data.

> *That didn't work either, because somewhere the addresses weren't exactly the same.* [ePA_19a_23_male]

These administrative challenges are experienced as particularly burdensome, as they cannot be overcome through personal technical skills or increased effort.

Phase 4: Interruption

Even after successfully completing individual steps, access to the ePA is often not enabled immediately but delayed due to postponed feedback, postal mailings, or time-limited activations. As a result, the registration process is not experienced as a continuous flow but as a sequence of separate steps that extend over several days or weeks.

> *It wasn't just one day; it was several days, because I (...) still had to wait for an activation letter.* [ePA_17a_32_male]

These temporal interruptions force users to repeatedly resume the process. After each pause, they must reorient themselves, recall previously completed steps, and reconstruct the current status. Repeated interruptions have a direct impact on motivation. The initial willingness to invest effort into the setup diminishes over time when the process stretches across longer periods. The need to re-enter a complex technical procedure after days or weeks is perceived as an additional burden and often results in abandonment.

> *I also failed at some point during authentication and then I just gave up.* [ePA_1a_34_male]

In combination with the previously described technical and administrative barriers, these interruptions contribute substantially to the perception of the setup process as lengthy and disproportionately cumbersome.

> *I experienced that as extremely complicated (...). Very, very rigid.* [ePA_17a_32_male]

Phase 5: Transition to Initial Use

Participants' accounts also provided limited insight into what occurred immediately after successful setup and authentication. Formal access did not necessarily lead to initial or continued engagement with the respective ePA application. Despite completing the access process, some participants reported only sporadic or no subsequent use. In the transition to actual use, it becomes apparent that successfully completing registration and authentication does not automatically lead to sustainable integration of the ePA application into users' everyday lives. Instead, the step from formal access authorization to actual, routinized use often fails to materialize. Despite overcoming multiple hurdles, participants report only sporadic or completely absent use of the application. For these participants, completion of setup marked the end of an effortful access process but not necessarily the beginning of regular application use.

A central reason for this lack of subsequent engagement was the limited perception of an immediate benefit. Many participants are unable to identify a clear added value after successful setup that would justify continued engagement with the ePA.

> *I installed it, but I never used it, because I didn't see any benefit in it.* [ePA_13a_37_female]

The app was not always experienced as an integral part of medical care or personal health management but rather as an optional add-on whose immediate relevance was unclear. Consequently, successful access did not necessarily result in initial or continued engagement with the respective application.

XSL•FO
RenderX

Cross-Phase Influencing Factors

Across all phases, participants drew on individual coping resources to navigate unclear instructions, coordinate multiple technical components, resolve unexpected problems, and resume interrupted procedures. These resources included digital competence, prior experience, persistence, and self-efficacy. This was explicitly reflected upon by participants.

> *If I didn't have a certain persistence or digital affinity, I probably would have given up.* [ePA_6a_67_male]

The registration process was therefore often experienced as an individual problem-solving project without systematic support.

> *I basically muddled through it on my own.* [ePA_12a_49_female]

Accumulation of Barriers Across the Access Process

Comparison across the 5 phases indicated that barriers could become consequential through their accumulation rather than through any single requirement. Unclear or outdated information during orientation meant that some participants entered the process without knowing which applications, documents, devices, or authentication procedures would be required. During technical entry and verification, they then had to coordinate multiple applications, identification services, passwords, PINs, and technical prerequisites. When technical failures, inconsistent administrative data, or postal procedures interrupted progress, previously completed steps sometimes had to be repeated. Each interruption therefore created additional coordination work and required participants to reorient themselves within the process.

These recurring sequences provide a process-oriented explanation of how access could become increasingly burdensome. Technical or administrative problems did not only affect the step in which they occurred; they could also prolong the pathway, require repeated attempts, and contribute to frustration or disengagement. Individual resources such as digital competence, prior experience, persistence, and self-efficacy helped participants navigate these demands but did not prevent technical or organizational failures. The findings therefore locate access difficulties in the alignment of user actions, technical components, and organizational procedures. When these components were not coherently connected, participants had to compensate through additional coordination and problem-solving work.

Variation Across Insurers, Devices, and Authentication Pathways

Participants were insured with 11 different statutory health insurers and used both iOS and Android devices. Cross-case comparison indicated that the central process-related difficulties were not confined to a single insurer or operating system. Unclear guidance, coordination between multiple technical components, repeated verification steps, and interruptions were described across different application and device constellations. No consistent pattern indicating systematically greater difficulties with either iOS or Android was identified. Other barriers were conditional on the authentication route used. Near-field communication (NFC) capability was relevant when electronic identity cards or electronic health cards were used for authentication. The need to request a health card PIN or wait for an activation letter applied only to pathways requiring these credentials. Problems with redirects or switching between apps arose when external identification services or separate authentication apps were involved. Administrative inconsistencies, such as differences in address data, could prevent verification independently of device type. Because individual insurers were represented by only a small number of participants and authentication routes were not distributed systematically across the sample, the study was not designed to compare or rank specific insurers, apps, operating systems, or authentication methods. The findings therefore distinguish between broadly recurring and pathway-specific barriers but do not support conclusions about the relative performance of individual implementations.

Discussion

Principal Findings

This study examined how individuals with statutory health insurance experienced setup and authentication for insurer-provided ePA apps and which challenges affected successful access to the ePA. The results show that setting up the ePA is not perceived as a single, completed step but rather as a sequential process that spans several stages separated in terms of time and organization. The fifth phase, transition to initial use, should be interpreted as an immediate downstream consequence of the access process rather than as an analysis of sustained adoption or integration into everyday practice. Informational, technical, administrative, and temporal difficulties may interact across these stages, requiring users to repeatedly coordinate components, resolve problems, and resume interrupted procedures. The results are consistent with international studies on EHRs, which also report heterogeneous use and complex barriers to access [27].

At the beginning of the access process, participants encountered limitations related to incomplete, unclear, or outdated information. This finding is consistent with international research emphasizing the importance of information for access to patient-facing EHR systems [6,7,28]. Within the present process model, orientation was not merely a preliminary question of awareness. It influenced whether participants understood which applications, documents, technical requirements, and authentication steps would be required. Insufficient orientation could therefore increase the coordination work needed during technical entry and verification and contribute to the accumulation of burdens across subsequent phases.

The inductively identified phases indicate that challenges do not arise from isolated technical problems alone but rather from the interaction between technical systems, organizational structures, and user practices. The ePA registration process comprises several interrelated components: digital infrastructures (eg, applications, authentication, and identity services), organizational actors and procedures (eg, health insurers, identity verification processes, and postal delivery of access credentials), as well as the work required from users to understand, coordinate, and repeatedly navigate these components. When

XSL•FO
RenderX

these components were not coherently aligned, difficulties could extend beyond the phase in which they initially occurred. Unclear requirements increased the coordination required during technical entry, technical or administrative failures interrupted verification, and waiting periods required users to resume the process after temporal gaps. Repeated attempts and prolonged effort could subsequently contribute to frustration and disengagement. The phases should therefore not be understood as independent categories or as a uniformly linear sequence, but as an interdependent process in which difficulties may accumulate and return users to earlier stages. These findings are consistent with insights from implementation research, which demonstrate that the successful introduction of digital technologies depends not only on technical functionality but, to a significant extent, on their organizational embedding and the provision of clear, comprehensible user guidance [29].

Importantly, substantial difficulties were also reported by participants with moderate or high affinity for technology. The findings therefore cannot be explained solely by limited digital competence. Participants' knowledge, prior experience, self-efficacy, and persistence helped them navigate the process, but these resources could not compensate for incompatible devices, malfunctioning applications, inconsistent administrative data, or delayed activation procedures. Access should therefore be understood as emerging from the interaction between users' available resources and the informational, procedural, technical, and organizational demands created by the access process. These findings can be situated within the eHealth Literacy Framework, which conceptualizes engagement with digital health as an interaction between individual capabilities and the characteristics of digital systems and services [30]. The present study does not propose an alternative or extended literacy framework. Rather, it provides a process-oriented account of how this interaction unfolds during setup and authentication. User resources influenced participants' ability to interpret instructions, coordinate applications, solve problems, and resume interrupted procedures. At the same time, process design and technical and organizational conditions determined the demands they encountered and whether progression through the pathway was possible.

Conceptualizing authentication as a multistage obligatory passage point highlights that access depends on the successful alignment of users, devices, applications, identification services, health insurers, and administrative procedures [19]. The findings indicate that these components did not always operate as a coherent access arrangement. Participants had to bridge gaps between them by identifying the correct application, interpreting system feedback, coordinating authentication tools, resolving administrative inconsistencies, or resuming procedures after delays. Technical and administrative disruptions therefore became user-facing access barriers that required additional coordination and problem-solving work. Authentication should consequently be understood not as a neutral technical prerequisite but as a sociotechnical implementation stage that structures whether individuals can actively access a formally available national EHR infrastructure.

The findings raise equity-relevant concerns but do not provide direct evidence of differences in access between population groups. Participants described substantial demands related to digital competence, persistence, problem-solving, and access to compatible devices. Because the sample predominantly comprised motivated participants with moderate or high affinity for technology, most of whom ultimately accessed the ePA successfully, the study cannot determine how these demands affect groups with fewer resources. It is plausible that the identified requirements may be particularly consequential for individuals with fewer digital, material, linguistic, cognitive, or social resources. However, this represents an inference from the observed process demands rather than a direct empirical finding. This interpretation is consistent with international research showing that digital health technologies can reinforce disparities when effective access depends on unequally distributed resources [31-33]. Further research specifically sampling and comparing diverse population groups is needed to examine these equity implications.

Practical Implications

The findings indicate that barriers to ePA access are embedded in the overall architecture and sequencing of the registration process rather than in isolated technical malfunctions. Implementation efforts should therefore focus on reducing cumulative burdens that emerge across stages. The practical implications were structured according to the 5 phases of the access process and the cross-phase factors identified in the analysis. For each phase, 1 priority measure was linked directly to the corresponding empirical finding. An additional cross-phase measure addresses participants' reliance on individual coping resources throughout the pathway (Table 2).

XSL•FO
RenderX

Table 2. Practical implications to support access to the ePA[a] application.

Process phase	Empirical finding	Practical implications
Phase 1: orientation	Participants began registration without a clear understanding of the required applications, documents, PINs[b], device functions, or available authentication routes. Information was sometimes incomplete, outdated, or insufficient for specific situations.	Provide centralized, up-to-date, and pathway-specific guidance, including a preregistration checklist of all technical and administrative requirements.
Phase 2: technical entry	Switching between applications, identification services, and technical interfaces increased coordination work. Device requirements such as NFC[c] capability were not always communicated before the process began.	Minimize transitions between applications and clearly communicate device and system requirements before users enter the authentication pathway.
Phase 3: verification	Multistep verification, technical failures, unclear feedback, and inconsistencies in administrative data prevented users from completing authentication or required repeated attempts.	Simplify verification procedures and provide actionable error messages that identify the problem and explain the next step or available support.
Phase 4: interruption	Postal procedures, waiting periods, and technical disruptions interrupted progression and required users to reconstruct or repeat previously completed steps.	Preserve completed steps and enable users to resume the process after interruptions, supported by clear progress and status information.
Phase 5: transition to initial use	Successful registration did not necessarily lead to initial or continued use when participants could not identify an immediate practical benefit.	Provide a brief postregistration orientation showing relevant initial use cases and the information or functions available in the ePA application.
Cross-phase factors	Across the pathway, participants relied on digital competence, prior experience, persistence, and self-efficacy to understand requirements, resolve problems, and resume interrupted procedures. The process was often experienced as an individual problem-solving task without systematic support.	Provide consistent and easily accessible support throughout the access pathway, including telephone or in-person assistance, to reduce reliance on individual coping resources.

[a]ePA: elektronische Patientenakte.

[b]PIN: personal identification number.

[c]NFC: near-field communication.

Strength and Limitations

To the best of our knowledge, this is the first qualitative study to examine the setup and authentication process of the opt-out ePA in Germany from the perspective of people with statutory health insurance. The study provides detailed insights into process-related burdens that are often missed in survey-based research. The qualitative approach enabled the identification of cumulative barriers and their interaction across successive process phases and provided a nuanced understanding of how structural features of digital implementation influence access and the transition to initial use. At the same time, several limitations warrant consideration. The analysis is based on a purposively selected analytic subsample from a larger dataset, which limits the transferability of the findings beyond the study context. Participation was voluntary, and the sample predominantly comprised motivated participants with moderate or high affinity for technology. Moreover, 21 of the 23 participants had ultimately gained active access to the ePA application. The study may therefore underrepresent individuals who did not attempt registration, abandoned the process at an early stage, had limited digital experience, or lacked access to suitable devices or support. Consequently, the findings are well suited to demonstrating that substantial access difficulties can occur even among technologically confident and predominantly successful users, but they do not support conclusions about the prevalence of dropout or the experiences of socially, linguistically, cognitively, or digitally disadvantaged groups. The results are based on retrospective self-reports and may therefore be influenced by recall bias, particularly regarding the exact sequence of authentication steps, error messages, and waiting periods. The interviews captured participants' subjective reconstruction of the access process rather than direct observations of their interactions with the applications. Furthermore, the study reflects experiences from an early phase of opt-out implementation; subsequent procedural or technical changes may alter user experiences over time. Because the interviews did not systematically examine use over an extended period, the findings do not support conclusions about sustained adoption or the long-term integration of the ePA into everyday health management. Since the interviews were conducted in 2025 and additional or different registration options have been introduced since then, the results reflect the registration procedures in effect at that time.

Conclusion

This study explores access to the opt-out ePA as a multistage process rather than a single technical act. Obstacles may interact and accumulate in the areas of orientation, technical access, verification, interruption, and the transition to use, reflecting the interplay of infrastructure design, organizational processes, and individual coping resources. Formal availability therefore does not ensure straightforward access. More coherent process design, reduced fragmentation, and accessible support are needed to limit the extent to which successful access depends on individual coping resources. The equity implications of these process requirements should be examined in studies specifically designed to include and compare populations with different

XSL•FO
RenderX

levels of digital, material, linguistic, cognitive, and social resources.

Acknowledgments

The authors thank all interview partners and participants for their valuable contributions and time. The authors would like to thank the Associations of Statutory Health Insurance Physicians in Westphalia-Lippe, Schleswig-Holstein, Lower Saxony, and Berlin for their valuable support in facilitating participant recruitment. During manuscript preparation, generative AI was used exclusively for language editing purposes, including translation into English and grammatical correction.

Data Availability

The qualitative interview data generated and analyzed during this study are not publicly available because they contain sensitive information and may permit participant identification. Public sharing would not be compatible with the conditions of the ethical approval and participants' informed consent. Requests concerning access to selected anonymized data may be directed to the corresponding author and will be considered subject to ethical, legal, and data protection requirements. Abstract

Background: Early warning systems (EWS) have the potential to reduce heat-related health risks, yet few are designed specifically for vulnerable populations. Pregnant women and infants, often cared for by postpartum women, are particularly susceptible to heat-related illnesses. The MotherHeat Alert mobile app is a heat EWS specifically developed for pregnant and postpartum women.

Objective: This study aimed to assess the usability and effectiveness of the MotherHeat Alert in the Tshwane District, South Africa.

Methods: This prospective observational evaluation study included a cohort of 201 participants (100 pregnant and 101 postpartum) who were followed over a 6-month period. In addition, a questionnaire was administered at 3 time points (baseline, midpoint, and end point) to collect self-reported information on health, living situation, and heat exposure, among other parameters. Usability was evaluated in the end point questionnaire through a validated Post-Study System Usability Questionnaire (PSSUQ), using descriptive statistics. Effectiveness was assessed through changes in self-reported heat-protective behaviors between baseline, midpoint, and end point, as well as through end point assessments of heat-health knowledge increase and self-reported behavior change attributable to the intervention. Generalized estimating equations were used to analyze repeated measures of heat-protective behaviors, while descriptive statistics were used to summarize end point–reported knowledge gains and behavior change.

Results: Usability scores indicated high overall usability, with mean PSSUQ scores of 1.76 (SD 0.60) among pregnant women and 1.37 (SD 0.45) among postpartum women. Similar patterns were observed across most PSSUQ subscales, including system usefulness, interface quality, and information quality. Most self-reported behavior change due to alerts received through the app

XSL•FO
RenderX

was rated as large to very large by the pregnant women (47/70, 67%) and postpartum women (68/82, 83%). Nevertheless, comparing behavior change at baseline and end point mainly highlighted a decrease in protective behavior in both pregnant and postpartum cohorts. Self-reported knowledge increase among pregnant and postpartum women was reported as large to very large following the use of the EWS (55/70, 79% and 72/82, 88%, respectively). Importantly, however, attrition was substantial, particularly among pregnant participants, reaching 30% (30/100) in the pregnant cohort and 19% (19/101) in the postpartum cohort by end point.

Conclusions: The MotherHeat Alert app demonstrated positive outcomes in usability. Effectiveness showed conflicting results, with positive self-reports on behavior change and knowledge increase, yet a decrease in protective heat behaviors when comparing baseline and midpoint with end point results, likely due to seasonality effects. Nevertheless, these findings highlight the potential of tailored EWS to support heat adaptation among pregnant and postpartum populations. Successful implementation and scalability require careful consideration of contextual factors, further assessment of long-term usability and integration into existing health infrastructure.

pregnancy; postpartum period; hot temperature; mobile apps; digital health; maternal health; global warming; South Africa

Introduction

Heat exposure causes an estimated 546,000 deaths annually worldwide [1], and contributes to increases in morbidity, particularly among high-risk populations [2] such as pregnant women. With heat extremes becoming longer, more frequent, and more intense, heat extremes currently classified as rare will become increasingly commonplace [3,4]. Pregnant women face heightened physiological strain due to elevated core body temperature and metabolic demands, while postpartum women bear responsibility for protecting heat-vulnerable newborns who cannot thermoregulate effectively. Many women in Africa have limited or no protection against heat during pregnancy [5], outlining the urgent need to identify effective prevention and response measures in these regions [3]. Heat action plans and forecasts, including heat-related early warning systems (EWS), issue early alerts and advisories [6,7] and have been demonstrated to promote heat adaptation and save lives [7-10]. However, current EWS designed to reduce heat-related health risks remain largely generic [9,10]. Despite heat-health risks in pregnancy, no heat-health EWS has been systematically designed and evaluated for pregnancy and the perinatal period.

EWS are widely recognized as cost-effective tools for climate adaptation, integrating different aspects of risk knowledge, monitoring and warning, and communication and response capacity [8]. A central challenge for EWS effectiveness is risk communication; systems must ensure that people at risk receive, comprehend, and respond to the alerts [11] communicated at the community and individual level [12]. For EWS to function effectively across different geographies and cultures, they should integrate social and cultural perceptions shaping heat awareness, risk perception, protective behaviors, and coping strategies, while providing science-based and locally relevant warnings [8]. Additionally, warnings issued without advice on responses are less effective [13]. Evidence from sub-Saharan Africa suggests that digital health interventions are most successful when they are simple, low-cost, and aligned with local contexts and languages [8,14,15]. Successful implementation further depends on user attitudes and behaviors and cultural acceptance [16]. Interventions must therefore be people-centered, context-sensitive, and coproduced with communities and local partners to ensure warnings are understood and acted upon [8,14,15]. Integrating such systems into existing digital health strategies may further support adoption and sustained engagement [14].

While there seems to be some awareness regarding heat warnings and high temperature forecasts among the general population, taking protective actions is less common [17], particularly among individuals who do not see themselves as at risk [13]. There is a demand for assessing the effectiveness of interventions to determine their ability to change knowledge, awareness, and behavior. Limited awareness of heat-induced health risks poses a major challenge for heat EWS [10,18]. Increasing the understanding of these risks and adopting small behavior changes could significantly reduce heat-induced morbidity and mortality [18]. Pregnant women exposed to cues to action are more likely to exhibit positive adaptation behaviors in response to heat, influenced by the awareness of vulnerabilities and their risk perception [18]. Therefore, effective communication of information enhances awareness while also significantly leading to adoption of adaptive behaviors [18]. Furthermore, research stresses the importance of assessing the effectiveness of heat EWSs, not just overall, but of specific interventions, particularly targeting vulnerable populations [10]. Improving the design and implementation of EWS directly enhances their effectiveness [10] and usability, which refers to user satisfaction within a defined intended use and context of use [19].

This study evaluates the usability and effectiveness of a mobile heat EWS app implemented in a South African context, with messages co-designed with pregnant and postpartum women. It is part of the larger Heat Indicators of Global Health (HIGH) Horizon project [20], which developed this EWS to help protect pregnant and postpartum women from heat exposure [21]. We assess whether the warning system is perceived as useful by its intended users, whether the mHealth app can improve awareness of the adverse health consequences of heat during and shortly after pregnancy, and whether it supports behavior change toward more protective heat-health practices.

RenderX

Methods

Study Design and Setting

We conducted an intervention cohort study to evaluate the usability and effectiveness of a personalized heat-health EWS, MotherHeat Alert, among 100 pregnant and 101 postpartum women in South Africa. As part of the larger HIGH Horizons project [20], the study was implemented between October 2024 and August 2025 at a community health center (CHC) in Tshwane, Gauteng Province, South Africa. The district is predominantly urban, with large informal settlements. Housing consists of formal houses, backyard rooms, and informal dwellings, most of which lack consistent access to cooling infrastructure. The telecom industry reports that almost 98% of mobile connections in South Africa are connected via 3G, 4G, or 5G mobile networks [22]. Average daily outdoor temperature was estimated using Copernicus Climate Data for coordinates near the health facility during the peak summer period (December 2024 to January 2025), when temperatures are typically highest in the study setting. During this period, average monthly maximum temperatures ranged from 26.9°C to 27.4°C, with 19 days measuring above 30°C and 3 days above 35°C.

Study Participants

A total of 2 cohorts were enrolled in this study:

1. Pregnant women: Confirmed pregnant, in the second trimester of pregnancy as assessed by a registered health worker, aged 18 years and older, and attending antenatal care services at the CHC.
2. Postpartum women: Women aged 18 years and older, with a live-birth infant in the past 3 months or women with a child aged 6-9 months of age, and recruited from the postnatal care services or well-baby and immunization clinics at the CHC.

Additionally, all participants needed to own a smartphone that could run the MotherHeat Alert app, intend to remain in the study area for the next 6 months, and be able and willing to provide written informed consent for study participation.

Sampling and Recruitment

Convenience sampling was used to recruit participants, with efforts made to cover diversity in age and demographic background. Recruitment flyers and posters were displayed in the maternity unit and health facilities, containing brief details about the study and contact details. Languages spoken throughout recruitment were English, Ndebele, Sepedi, Setswana, Zulu, and Sesotho.

Study Visits

Questionnaire data were collected at 3 study visits (baseline, 2 months, and 6 months). The enrollment visit (~60 to 90 minutes) included informed consent, administration of the baseline questionnaire, and a 30-minute training session to install and configure the MotherHeat Alert app and show participants how to use the app. User profiles were set up within the app to include age, body weight, and height. Follow-up visits occurred at 2 and 6 months post enrollment, January-March and June-August, respectively. Slight changes were made between trial registration and the implementation of the study by introducing visit windows to reduce the risk of missed visits and participant dropouts. Each of these sessions lasted approximately 60 minutes and included the questionnaire administration. At the 6-month visit, participants also completed the Post-Study System Usability Questionnaire (PSSUQ) to assess the usability of the EWS (listed in Multimedia Appendix 1). At any time during the study period, participants could complete a short in-app survey, consisting of 7 questions. This survey was optional and assessed heat symptoms, perceived heat, and app usability, collecting real-time submission of user responses.

Data Collection and Analyses

Quantitative data were collected through structured, interviewer-administered questionnaires using Research Electronic Data Capture (REDCap; Vanderbilt University) [23] and through the continuous in-app data collection. Questionnaires captured sociodemographic information, medical and obstetric history, knowledge and protective behaviors linked to heat risks, data on the economic burden and app feasibility, and acceptability and usability, particularly at the end point visits. The in-app data included timestamps of interactions, app usage metrics, and responses to usability and heat-related questions. For this study, usability, knowledge increase, and behavior change related to the intervention were of main interest. Furthermore, the EWS captured heat parameters, which were used to analyze 2 in-app survey items, as described in more detail in the following section. The current Universal Thermal Climate Index (UTCI), a comprehensive heat stress index integrating air temperature, humidity, solar radiation, and wind speed and including models estimating clothing insulation and metabolic heat production [24], was used to capture the environmental heat exposure in this study. The app retrieved local weather forecast data daily at approximately 6 AM, but an alert was only generated and issued when the predefined heat threshold was met. Alert generation was determined locally on participants' devices.

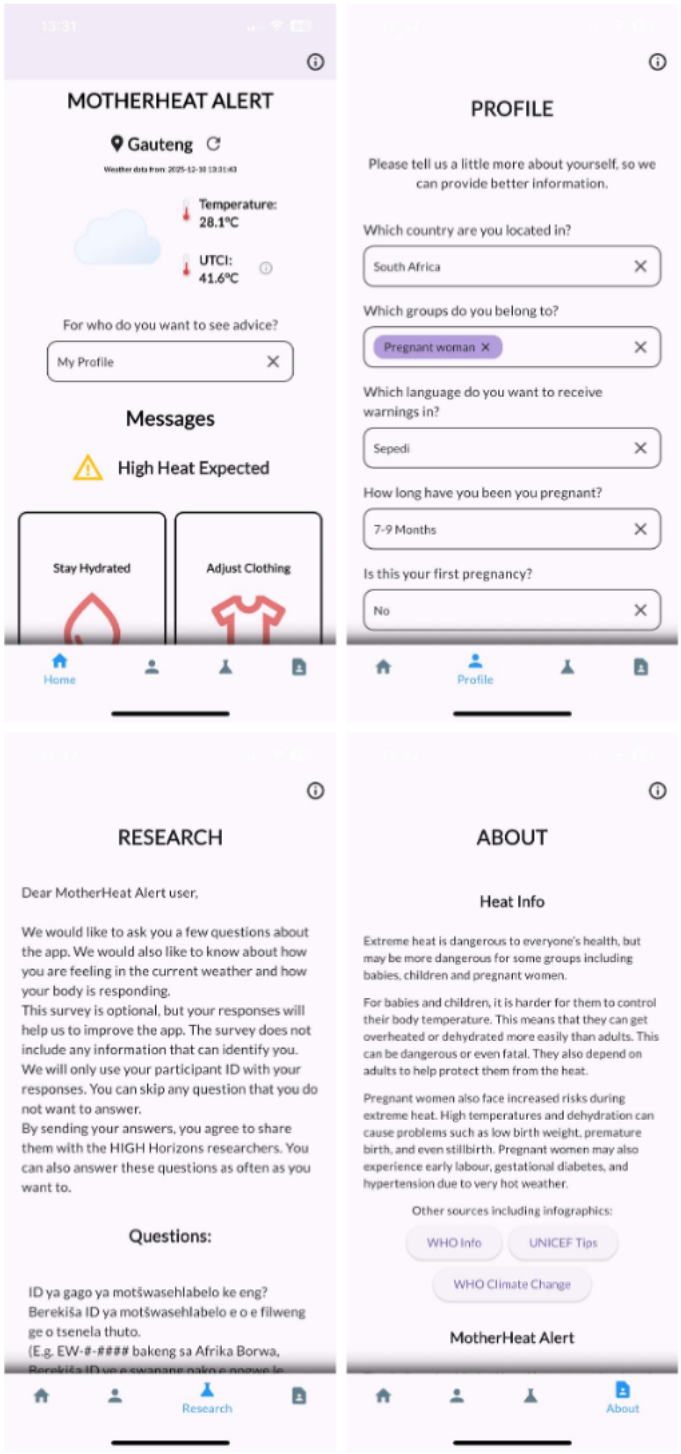
Outcome Measures: Usability and Effectiveness

Usability was assessed through a validated PSSUQ administered at the end point visit. The PSSUQ is a 16-item scale that assesses user satisfaction through an overall evaluation of the system used [25]. Besides its overall score, it has 3 subscales that have been assessed individually: system usefulness, information quality, and interface quality. All scales have a maximum possible score of 7, with lower numbers indicating better usability [25]. Effectiveness in the context of this study refers to the ability of MotherHeat Alert to change knowledge and awareness of heat-health risks [26]. This was assessed through comparisons between end point and baseline scores. Effectiveness was therefore evaluated based on (1) heat-protective behavior change, for instance, through the question "Thinking about the last day when it was really hot, what did you do to keep yourself cool?" and (2) knowledge increase on heat and health following the intervention period, for instance, through the question "From your use of the app, do you think that your knowledge about the effects of heat on your health has increased?" Table S1 in Multimedia Appendix

XSL•FO
RenderX

1 provides a visual illustration of the usability and effectiveness concepts and how these were assessed. All analyses were conducted using SPSS version 30.0 (IBM Corp).

Statistical Analysis



Most self-reported usability and knowledge increase perceptions were assessed at end point, using descriptive statistics. Binary logistic generalized estimating equations (GEE) models were used on 2 questionnaire items, namely "Thinking about the last day when it was really hot, what did you do to keep yourself cool?" and "Thinking about the last day when it was really hot, what did you do to protect your baby from the heat?" to assess whether a significant behavior change was detected by comparing baseline and end point results. We further used 2 methods to assess the in-app survey items: a generalized linear mixed model (GLMM) to evaluate survey items with large discrepancies in repeated responses and a linear mixed effects model with random intercepts, which accounts for substantial between-individual differences at baseline (Table S1 in Multimedia Appendix 1 provides further details regarding choice of statistical model and time of data collection).

The Heat Health EWS: MotherHeat Alert

The MotherHeat Alert app is a mobile EWS for Android (Google LLC) and iOS (Apple Inc.) users that provides real-time, localized heat warnings with tailored health advice to improve awareness of heat-related health risks and promote protective behavior [26]. The app served as an intervention that integrates environmental data (UTCI temperature, air temperature, humidity, solar radiation, and wind) with the user's gestational status to deliver personalized alerts and recommend specific, locally adapted protective actions (refer to Figure 1 for app interface). It used a 7-day UTCI daily forecast and issued push notifications at 6 AM whenever at least one of the following 7 days was predicted to exceed the predefined heat alert threshold of 27.3°C UTCI. Individual parameters including age and BMI could also be added to the EWS to further personalize messaging. Participants selected profiles, choosing between pregnancy or postpartum stages, which in turn determined the content and timing of heat alerts and messages. At a minimum, the EWS aimed to increase heat risk awareness and support behavior change, such as using specific cooling techniques, more suitable clothes, and how to stay hydrated, among others, during hot, high-risk periods. In this study, the EWS app was provided free of charge and delivered response messages with locally applicable guidance in local languages.

XSL•FO
RenderX

Figure 1. The MotherHeat Alert interface. From left to right, top to bottom: the home screen, the profile screen, the research screen, and the about screen.

Patient and Public Involvement

A co-design process was used to develop the messages used in the MotherHeat Alert app. This included photovoice workshops with pregnant and postpartum women recruited from the study site to develop messages based on their lived experiences [27]. The draft messages were then presented to community health workers based at the CHC in 2 focus group discussion sessions to enable triangulation and further contextual validation. Further refinements were made in consultation with expert reviewers. This process helped ensure that the EWS was grounded in lived experiences while being informed by professional expertise.

Ethical Considerations

Both the University of Witwatersrand Human Research Ethics Committee (HREC) in South Africa (approval number 240606)

XSL•FO
RenderX

and district approval were granted to conduct the study in a Tshwane health facility. The study was registered with the South African National Clinical Trial Registry (DOH-27-032025-5623), as part of the European Union (EU) and United Kingdom–funded HIGH Horizons project. All participants provided written informed consent. Data were fully anonymized or pseudonymized. Each participant was assigned a unique participant identification number. Participants were reimbursed ZAR400 (±US $25) for attending each study visit.

Results

Overview

In total, 280 women were screened for eligibility. Of these, 209 (74.6%) met the inclusion criteria and provided informed consent. Reasons for nonenrollment include not having compatible smartphones (26/280, 9.3%), not planning to remain in the area for 6 months (14/280, 5%), or not willing and/or able to provide written consent (51/280, 18.2%; note that reasons are not mutually exclusive). Of the 209 women who were enrolled, 8 discontinued early: 5 were unreachable after enrollment, 1 declined to install the app, and 2 withdrew after enrollment without providing a reason. Ultimately, 201 participants (100 pregnant and 101 postpartum) were included in the analyses; however, 25 (12.4%) did not complete the midpoint visit, and 50 (24.9%) did not complete the end point visit. Enrollments occurred between October 2024 and January 2025, while 2-month follow-up (midpoint) and 6-month follow-up (end point) visits were conducted between January 2025 and March 2025 and June 2025 and August 2025, respectively. For the pregnant cohort, the number of participants retained was 100 at baseline, 93 at midpoint, and 70 at end point. For the postpartum cohort, 101 were included at baseline, 83 at midpoint, and 82 at end point. Due to the privacy-by-design architecture of the system, alert generation was not recorded on the central server; therefore, the number and timing of alerts displayed to individual participants could not be determined.

At baseline, the median age for both pregnant and postpartum participants was 29 (IQR pregnant women 25-34; IQR postpartum women 24.5-33) years. Most participants completed high or secondary school (117/201, 58.2%), and half were unemployed but looking for work (100/201, 49.8%). Most participants (193/201, 96.0%) reported owning a phone that was not shared with other family members. Almost all (n=200) participants reported using apps on their phone, mostly for social media (198/201, 98.5%) and messaging (92/201, 45.8%; Table 1). Furthermore, 55 of 201 (27.4%) participants reported having a pregnancy or baby monitoring app on their phone, and 79 of 201 (39.3%) participants received pregnancy or baby growth and development messages on their phones (eg, MomConnect). At baseline, prior to the MotherHeat Alert intervention, the largest proportion of participants reported never discussing heat-related health concerns with the community (96/201, 47.7%; Table 2), and only a few participants mentioned knowing about any community programs or public health messages about heat safety (9/201, 4.5%; Table 2). Among the postpartum cohort, very few participants reported knowing about the effect of heat on themselves during pregnancy or the postnatal period (10/101, 9.9%) and their baby (9/101, 8.9%; Table 2). Around half of the participants (102/201, 50.7%) reported that it is hotter inside compared to outdoors (Table 2). A large proportion (65/201, 32.3%) reported wanting to take additional particular heat-protective measures but were unable to do so.

Usability

With lower PSSUQ scores indicating better usability, the summed overall score of PSSUQ (questions Q1-Q16) in the pregnant cohort ranged between 1 and 3.44 (mean 1.76, SD 0.60; n=70) and 1 and 2.85 (mean 1.37, SD 0.45; n=81) in the postpartum cohort (Figure 2). The PSSUQ score on system usefulness (Q1-Q6) ranged between 1 and 2.83 (mean 1.34, SD 0.51; n=70) for the pregnant cohort and 1 and 2.83 (mean 1.28, SD 0.39; n=81) for the postpartum cohort. The PSSUQ score on information quality (Q7-Q12) was higher for the pregnant cohort and ranged between 1 and 5.33 (mean 2.52, SD 1.19; n=70) but lower for the postpartum cohort, ranging from 1 to 3.67 (mean 1.48, SD 0.64; n=81). Finally, the PSSUQ score on interface quality (Q12-Q16) ranged between 1 and 4.0 (mean 1.31, SD 0.63; n=70) for pregnant and 1 and 3.25 (mean 1.35, SD 0.53; n=81) for the postpartum cohort (Figure 3). To account for the large dropout rate across the study (Figure 4), we conducted a sensitivity analysis for the total usability-related scores, comparing baseline to the end point. Overall, 2 different scenarios were assessed, one assuming that dropouts occurred due to low usability ratings and the other assuming that dropouts occurred due to other external reasons.

Baseline comparisons between participants who dropped out and those who remained in the study showed no significant difference in age (independent-samples 2-tailed *t* test), self-rated general health, presence of chronic health conditions, perceived indoor heat, housing type (formal vs informal dwelling), or perceived seriousness of heat for themselves or their infants (chi-square tests; all $P<.05$). There was some indication of differences by educational attainment, with a nonsignificant overall association (chi-square test, $P=.09$), but evidence of a significant linear trend ($P=.02$), suggesting lower dropout rates among participants with higher levels of education. Furthermore, sensitivity analyses were conducted to evaluate the effect of missing end point usability data under alternative assumptions. In the worst-case scenario, dropouts were assigned the maximum PSSUQ score of 7, representing the poorest usability and assuming that withdrawal was related to poor user experience. In the as-usual scenario, dropouts were assigned scores comparable to those who completed end point assessment, assuming that dropouts occurred for reasons unrelated to usability. Results were robust under the as-usual assumption (mean 1.53, SD 0.52, 95% CI 1.46-1.61; n=201). Under the worst-case assumption, the mean score was higher (mean 2.91, SD 2.41, 95% CI 2.57-3.24; n=201), indicating poorer usability and greater variability; however, it did not change the overall interpretation of the findings.

For the in-app question "Was the message you received relevant for your situation" (yes or no), current UTCI significantly predicted the likelihood of participants finding messages relevant: for every 1°C increase, the odds of reporting that a message was relevant increased by ±5% (odds ratio [OR] 1.05, 95% CI 1.01-1.09). The model highlighted significant between-person variability in baseline relevance rating (Var=3.59; $P<.001$). For the in-app question "On a scale of 1 to 5, please rate how easy you have found it to use the app" (1=easy, 5=difficult), a comparison of novice users with experienced users assessing whether the perceived ease of use changed with experience showed that the effect of time was

XSL•FO
RenderX

statistically significant ($F_{1,6335}$=76.18; P<.001), indicating that perceived difficulty decreased as participants used the MotherHeat Alert over time. Importantly, however, this statistically significant change was very small in magnitude (marginal R^2=0.007), where most variation can be explained by the differences across users (conditional R^2=0.63). This suggests that 0.7% of the variance in difficulty can be explained through the repeated use over time.

Effectiveness

Knowledge Increase

The largest proportion in both pregnant and postpartum cohorts self-reported a large to very large knowledge increase (55/70, 78.6% and 72/82, 87.8%, respectively) on the effects of heat on pregnant women's health (Table 3). The postpartum cohort also indicated a large to very large knowledge increase (72/82, 87.8%) on the self-reported effects of heat on the baby's health.

Table 3. Self-reported knowledge increase due to early warning systems app reported by pregnant and postpartum cohort.

Self-reported knowledge increases due to EWS[a] use	Values
Pregnant cohort: effects of heat on pregnancy health, n (%)	
No-slight increase	2 (2.8)
Moderate increase	13 (18.6)
Large-very large increase	55 (78.6)
Do not know	0 (0)
Total	70 (100)

Moderate increase	9 (11)
Large-very large increase	72 (87.8)
Do not know	1 (1.2)
Total	82 (100)

[a]EWS: early warning systems.

Behavior Change

The item assessing "Thinking about the last day when it was really hot, what did you do to keep yourself cool?" contained 17 potential response options. In a GEE model, after adjusting for maternal age and education, a significant behavior change was noted for 8 options comparing end point (6-month follow-up after app introduction) to baseline (preapp introduction) in paired analyses (Table 4). For both pregnant (n=70) and postpartum cohorts (n=82), the following behaviors showed statistically significant shifts toward less frequent use after introduction of the app: drinking more water, drinking more fluids, bathing more, using more light and loose clothing, opening windows, and wearing a hat. For the pregnant women cohort, eating more fruits and increased use of a fan also decreased significantly between baseline and end point. For the postpartum cohort, working less and staying indoors decreased significantly between baseline and end point. A total of 4 response options—using Mcako or clay or ibovu (a type of clay that is high in minerals and traditionally used as skin protection from sun exposure), air conditioning, using an umbrella, and did nothing—could not be analyzed due to an insufficient number of cases across groups for statistical testing. Importantly, all the comparisons between baseline and end point indicate a negative change, highlighting that less protective heat action had been taken at end point compared to baseline (Table 4). Comparing midpoint (2-month follow-up after app introduction) to baseline, a similar, yet less pronounced trend was discerned, with 2 response options showing a significant decrease in protective behavior in the pregnant cohort, including using a fan and wearing light and loose clothing. In the postpartum cohort, 7 behaviors indicated a significant decrease, including drinking other fluids, working less, bathing more frequently, wearing light and loose clothing, opening windows, wearing a hat, and staying indoors (Table S2 in Multimedia Appendix 1). In this GEE model, 2 covariates were controlled for: maternal age and education [28-31] since both have consistently been associated with more protective health behavior. Effect estimates of a stratified analysis of these covariates can be found in Table S3 in Multimedia Appendix 1 for end point results and Table S4 in Multimedia Appendix 1 for midpoint results. Statistical significance of the correlations did not differ between crude and adjusted models. At end point, almost all participants from the

XSL•FO
RenderX

pregnant (66/69, 96%) and postpartum (72/82, 88%) cohorts indicated that these measures were taken because they were alerted by the app.

The item "Thinking about the last day when it was really hot, what did you do to protect your baby from the heat?" contained 13 answer options, where giving the baby more water, giving the baby more fruit, and seeking shaded or cool areas yielded a positive behavior change, whereas dressing the baby in light and loose clothing and opening windows showed a decrease at end point in the adjusted model (Table 5). Again, the midpoint results yielded a similar pattern, where seeking shaded or cool areas and other measures showed an increase in this adaptive behavior, and dressing the baby in light and loose clothing, opening windows, and keeping the baby indoors showed a decrease in this behavior in the adjusted model (Tables S5 and S6 in Multimedia Appendix 1). Most postpartum women (72/82, 87.8%) indicated that these protective measures were taken because they were alerted by the app. The largest proportion of self-reported behavior change due to the alerts received through the app rated this change as large to very large: 67.2% (47/70) in the pregnant cohort and 82.9% (68/82) in the postpartum cohort (Table S7 in Multimedia Appendix 1).

The in-app question "Did you follow the advice provided? (yes or no)," which was linked to current UTCI, significantly predicted the likelihood of following advice; for every 1°C increase in current UTCI, the odds of following advice increased by ±14% (OR 1.14, 95% CI 1.09-1.20). The model highlighted significant between-person variability in the baseline following advice rating (random intercept var=5.072; *P*<.001).

Discussion

Principal Findings

This study assessed the usability and effectiveness of an EWS aimed at reducing heat-related health risks among pregnant and postpartum women.

Usability results indicated that the MotherHeat Alert was considered useful and was well accepted by users. The effectiveness findings of the MotherHeat Alert suggest that engagement with the EWS led to self-reported increases in adoption of heat-protective knowledge and behavior. Comparisons of actual self-reported heat-protective behaviors at baseline and end point showed that these behaviors largely decreased by the end of the 6-month intervention period. This decrease could also be identified to a lesser extent at the 2-month midpoint results. Importantly, these results should be interpreted with caution, as midpoint and end point assessments were conducted during cooler months, introducing seasonal variation as an important confounder. In addition, approximately one quarter of participants were lost to follow-up between baseline and end point.

Usability of the MotherHeat Alert

Successful digital health interventions rely on effective integration, adoption, and sustained use by their intended users [32,33]. The Technology Acceptance Model emphasizes perceived usefulness and ease of use as key determinants of technology adoption [34,35]. The positive usability and knowledge outcomes observed in this study support the relevance of these principles to heat-related EWS. Usability, assessed using the PSSUQ questionnaire, was high overall, with system usefulness, information quality, and interface quality all scoring above average compared to norms reported by Lewis and James [25]; the system usefulness subscale scored highest and the information quality subscale lowest. Although similar patterns were observed between pregnant and postpartum cohorts, postpartum women consistently rated the EWS's usability higher, compared to pregnant women, and a greater variability in responses was typically observed in the pregnant cohort. A total of 2 additional in-app usability indicators, "perceived relevance of warnings" and "ease of use," showed significant changes over time. The "perceived relevancy of warnings" increased with rising temperatures, with a 5% increase in likelihood per 1°C rise, suggesting that alerts aligned well with users' lived experiences. "Ease of use" improved over time, indicating that with repeated use and increased familiarity, the EWS was perceived as easier to use, a trend that has been seen in other studies [36,37].

Effectiveness of the MotherHeat Alert

Most intervention studies in African settings focus on health promotion and disease prevention, aiming to improve health knowledge and encourage behavior change [14]. These generally report positive results [14], which is reflected in the outcomes of this study where women expressed interest in weather apps and general involvement with the EWS. Education and awareness building are among the most common and effective apps of digital health interventions [32]. Behavior change is therefore a suitable measure of effectiveness, as education and knowledge shaping are widely used and effective behavior change techniques [38,39]. High engagement with the EWS supports its effectiveness, as 95.7% (66/69) of pregnant participants and 87.8% (72/82) of postpartum women reported taking protective actions in response to alerts. Effectiveness,

XSL•FO
RenderX

measured through self-reported knowledge increase, indicated that at end point, 78.6% (55/70) of pregnant women showed a large to very large knowledge increase on the effects of heat on their own health. For the postpartum cohort, 87.8% (72/82) reported a large to very large knowledge increase of the effects of heat on their own and their baby's health. The warnings issued through the MotherHeat Alert resulted in preventive actions, suggesting that the recommended measures were practical and feasible for participants to carry out.

Nevertheless, when comparing baseline to end point outcomes, 9 of 17 behaviors reduced significantly among pregnant participants; a similar, but less pronounced trend was observed when comparing midpoint to baseline. Seasonal variation is an important confounder when interpreting the observed decrease in protective behaviors. Baseline assessments were conducted from October 2024 to January 2025, covering the transition period into warmer and early summer months; midpoint assessments from January to March 2025, spanning the later summer period and the early transition into cooler months; and end point assessments from June to August 2025, during the cooler months. Baseline and end point assessments therefore occurred during substantially different climatic conditions, and changes in heat-protective behaviors cannot be attributed to the intervention alone but must be interpreted in the context of seasonal variation. This would also explain why the reduction in heat-protective behavior was less pronounced comparing midpoint to baseline than end point to baseline. As days became cooler, there was no need for pregnant and postpartum women to apply cooling measures as the ambient temperatures were not high enough to warrant adaptive behavior. Fewer cooling behaviors during cooler months should therefore not necessarily be interpreted as poorer adherence or reduced intervention effectiveness but may instead represent an appropriate behavioral response to lower heat exposure. This interpretation is supported by our in-app data, which showed greater adherence to warning advice at higher temperatures, indicating that perceived risk intensifies responsiveness. As the MotherHeat Alert and heat-health apps and EWS more broadly are most relevant during warmer periods, strategies to reengage and retain users ahead of following heat seasons should therefore be considered. Future evaluations should compare behavioral outcomes during similar climatic conditions, for example by conducting baseline and follow-up assessments within the same warm season or across multiple summers for clearer findings and interpretation. For protective behaviors exhibited by postpartum women directed toward infants, a similar negative trend, highlighting less protective behavior at end point, could be identified in some behavior responses, yet a positive trend, indicating more protective behavior, could be seen in others. Among postpartum women, the ability to work less and stay indoors may have been affected by the urgency of returning to employment after childbirth or a need to seek employment as financial responsibilities have increased.

The observed reductions in self-reported protective behaviors should not necessarily be interpreted as indicating reduced engagement with heat-protective practices. Although end point assessments took place during the cooler season, participants were asked to report behaviors undertaken on "the last day when it was really hot", rather than behaviors undertaken at the time of assessment. During the cooler season, this may have required participants to recall behaviors from further back in time than during the warmer periods, potentially affecting the accuracy of their responses. In addition, social desirability may have influenced self-reported behaviors, particularly at baseline when participants may have been more inclined to report behaviors perceived as desirable or appropriate. Overall, it is further likely that at the start of the intervention, participants were more engaged and motivated to use a new technology, which may have temporarily increased both attention to the app and self-reported adoption of heat-protective behaviors. However, over time, the novelty of participation likely diminished as attention fatigue set in, and actual behaviors may have returned to preintervention patterns, contributing to lower observed heat-protective practices at midpoint and end point. Therefore, the observed changes may reflect a combination of seasonality, social desirability, and reduced motivation over time, rather than an intervention effect alone.

Limitations

This study has several limitations. Participation was limited to women [14] attending health facilities and owning smartphones, introducing potential selection bias and thereby excluding some of the most vulnerable populations. Convenience sampling through antenatal clinics may have introduced additional selection bias, so findings may not be representative of the broader population of pregnant and postpartum women in South Africa and should therefore be generalized with caution. As the MotherHeat Alert is a text-based EWS, which delivers warnings through written messages, illiterate individuals were likely excluded; literacy rates were not assessed. To increase inclusivity, EWS apps should ideally rely more on graphic messages or audio prompts. Additionally, local infrastructure constraints, such as unstable electricity supply to charge mobile phones, unstable network, shutting down phones to preserve battery power [16], or deleting the app to preserve storage space on end-devices, may have affected notifications, alerts, and system performance. Recruitment in this study was constrained as some women lacked smartphones, while others had devices with limited storage. Installing the app often required deleting photos or other apps, which some participants were unwilling to do. Furthermore, the EWS app required mobile data for daily temperature synchronization and warning delivery. Future EWS should ideally function without the requirement for mobile data or operate through agreements with telecommunication providers to waive data charges (ie, zero-rated app). Finally, all outcomes were self-reported, introducing the possibility of response and social desirability bias. Given the enrollment procedures, participants were aware of project aims, which may have influenced their responses. Furthermore, participant engagement in this study may have been influenced by monetary reimbursement, which may suggest that women in real-world settings may be less likely to install or use the app given these barriers.

Given that the study intended to assess usability and effectiveness over the short- and long-term, 6 months of follow-up was required. This resulted in seasonal timing of data collection becoming a limitation, where baseline data was

XSL•FO
RenderX

collected during warmer months, while end point measures occurred during colder months. This may partly explain the decline in reported protective behaviors. Furthermore, given that the proportion of adaptive behaviors reported at baseline was high, particularly among postpartum women, participants may already have adapted to heat exposure, such that explicit warnings added limited new information. Dropout rates in this study were substantial, and usability outcomes were therefore further examined using sensitivity analyses under 2 assumptions: a worst-case scenario, in which participants discontinued due to poor usability, and an as-usual scenario, in which dropouts were unrelated to EWS usability. Baseline characteristics did not differ significantly between participants who dropped out and those who remained, suggesting no clear evidence of systematic differences, thereby supporting the as-usual scenario. In addition, local contextual factors indicate that some participants may have discontinued the follow-up because women may return to their place or country of origin after receiving maternity care in South Africa [40]. It is also important to note that women reported wanting to take additional heat-protective behavior at baseline, but reported they were unable to do so. This finding, however, reflected their general perceived ability to protect themselves from heat, rather than their ability to follow the specific behavioral advice provided through the MotherHeat Alert, which was codeveloped with intended users to ensure that the recommended actions were practical and feasible within their context. Furthermore, the project-based design and limited timeframe restricted conclusions about long-term usability beyond the novelty effect of a new intervention, and about sustainability and scalability, which should be prioritized prior to consideration for mass roll-out. This structural limitation presents a common limitation of intervention studies in African contexts [14]. Evidence on cross-country uptake of the EWS, scalability, and continuity of digital health interventions in Africa remains weak, with most existing studies limited to pilot or small-scale implementations [14,34]. Finally, it should be noted that, to the best of our knowledge, the PSSUQ has not yet been validated in South Africa, although previous research has used the PSSUQ in South Africa [41] and other African countries [42].

Future Directions

Given the borderless nature of heat risk and its increasing severity, the development of a global heat EWS should be a long-term goal [8]. Despite their potential, few countries have heat-specific EWS, and no global system exists for the specific vulnerable groups. This represents a critical gap, particularly since the United Nations' Early Warning for All initiative aims to ensure effective EWS coverage by 2027 [43]. Currently, South Africa still issues heat warnings using absolute air temperature thresholds unrelated to health responses [44]. Future systems should be built around specific heat-health indicators, locally relevant, and integrated heat stress thresholds and codeveloped communication strategies. Greater attention is needed to gendered and intersecting vulnerabilities to ensure access to warnings [15]. Future research should prioritize rigorous impact evaluations, cost-effectiveness analyses, and qualitative studies on implementation context [14,32]. In addition, simplicity of design and modest objectives have repeatedly been associated with successful implementation in African contexts, since these products were least affected by contextual challenges [14]. Greater emphasis is needed on integrating the digital interventions into the existing health care infrastructure and addressing scalability [45]. Given the constraints of limited memory on mobile phones, together with the high use of social media among participants, stand-alone apps for heat-health warnings may not be the most efficient approach. Integrating these warnings into social media platforms may therefore be a more feasible and effective strategy.

Digital health interventions are generally received with optimism [14]. As mobile phone use is rapidly increasing in sub-Saharan Africa, the digital health technologies designed for this context follow suit [34]. Although evidence on long-term effectiveness and impact remains limited, this study demonstrates high effectiveness and usability of a heat-related EWS. Education and training have shown to reduce heat stress and illness [39], as shown in a study where digital technologies supporting maternal health in sub-Saharan Africa have contributed to improved maternal and infant health decision-making [16].

Conclusion

Overall, our study strengthens the growing evidence that well-designed, user-centered digital health technologies, including heat EWS, have high usability outcomes and contribute to knowledge gains in the context of climate-related health risks. However, the contribution of EWSs to improved health outcomes in broader contexts will depend on whether they are perceived as useful, easy to use, and whether social, cultural, and policy contexts have been considered during their implementation. This study demonstrates the potential of a co-designed heat-health EWS tailored toward pregnant and postpartum women to support protective responses to heat exposure. The intervention demonstrated high self-rated usability and perceived effectiveness among users. However, the observed decrease in heat-protective behaviors when comparing reported behavior at baseline compared to end point assessments should be interpreted with caution, as seasonal variation was linked to the follow-up visits through the study design, making it impossible to attribute behavioral changes to the intervention alone. Digital health technologies may play an important role in strengthening climate adaptation responses for maternal health. Focusing on the usability and effectiveness of EWS interventions, considering contextual relevance, assessing long-term usability beyond the novelty effect, and ensuring access for everyone by integrating these interventions into existing health systems is required to achieve this potential.

Acknowledgments

We thank Rose Refilwe Lamola, Celeste Madondo, Nondumiso Precious Mbatha, Mbalenhle Felicity Mvundla, and Kgomotso Reginah Mabidikama for their contributions to the implementation of the MotherHeat Alert and data collection. We also

acknowledge Birgit Kerstens for her continued organizational support within the HIGH Horizons project. ChatGPT (OpenAI) was used for refinement, correction, and editing of the manuscript to improve clarity of language.

Funding

This study was funded by the European Union's Horizon Framework Programme under grant agreement number 101057843. Project partner London School of Hygiene & Tropical Medicine is funded by UK Research and Innovation's Innovate UK agency (reference number 10038478). The funder played no role in study design, data collection, analysis and interpretation of data, or the writing of this manuscript.

Data Availability

The datasets generated and analyzed during this study are not publicly available due to sensitive health data and participant confidentiality but are available from the corresponding author on reasonable request.

Abstract

Background: Adolescents living with perinatally acquired HIV (PHIV) remain at risk of neurocognitive difficulties, yet access to valid neurocognitive tests is limited in sub-Saharan Africa (SSA), where most of this population resides. Tests that can be administered by nonspecialist personnel are culturally and linguistically appropriate for SSA's diverse populations and are brief enough for routine use are needed to expand access, but few such tools exist.

Objective: We adapted *NeuroScreen*, a brief tablet-based neurocognitive test battery, into Luganda and evaluated its validity and acceptability for use among Ugandan adolescents with PHIV.

Methods: In this cross-sectional validation study, 100 Ugandan adolescents aged 11 to 20 years (50 with PHIV; 50 HIV-negative controls) completed the Luganda- or English-language *NeuroScreen* battery and a commonly used traditional test battery. Participants were recruited from an existing longitudinal cardiovascular cohort at the Joint Clinical Research Centre in Kampala, Uganda. We examined convergent validity with correlations between the 2 batteries' individual and global *z*-scores, known-groups validity with unadjusted and age-adjusted group comparisons, criterion validity by examining classification agreement between the 2 batteries quantified with Cohen κ, and acceptability through self-reported technology use and ease of use.

Results: *NeuroScreen* and the traditional battery global *z*-scores were strongly correlated (r=0.75; P<.001). Correlations between tests assessing similar domains were generally small to moderate, and were strongest for processing speed, attention, and working memory. Adolescents with PHIV scored significantly lower than controls on global scores for both *NeuroScreen* (P=.008) and the traditional battery (P=.003), even after adjusting for age. Agreement between batteries in classifying participants ≤1 SD (κ=0.56) and ≤2 SD (κ=0.66) below the global *z*-score mean was moderate, with both batteries classifying more adolescents with PHIV than controls below these thresholds. Although fewer than half of participants (42/97, 43%) had previously used a tablet, most rated *NeuroScreen* as easy to use, and prior tablet experience was not independently associated with *NeuroScreen* performance after age adjustment.

Conclusions: The Luganda-adapted *NeuroScreen* demonstrated convergent, known-groups, and criterion validity in Ugandan adolescents with PHIV. By delivering automated administration, automated scoring, and standardized multimedia instructions in the local language on a portable tablet, *NeuroScreen* addresses several persistent barriers to neurocognitive assessment in low-resource settings, including shortages of specialist personnel, the time burden of traditional batteries, and the scarcity of

XSL•FO
RenderX

culturally and linguistically appropriate tools. The *NeuroScreen* battery was found to be highly acceptable among adolescents with little or no prior tablet experience. These findings add to a growing body of evidence supporting tablet-based assessment as a practical and scalable mobile health approach to expanding access to neurocognitive testing. Future research should evaluate test-retest reliability, sensitivity to change over time, normative benchmarks, and implementation within real-world clinical workflows.

Introduction

Globally, there are approximately 1.57 million (1,200,000-1,900,000) adolescents (10-19 y) living with HIV, most with perinatally acquired HIV (PHIV) and living in low- and middle-income countries (LMICs), with approximately 85% living in sub-Saharan Africa (SSA) [1,2]. Greater access to more effective antiretroviral therapy (ART) has greatly improved their health outcomes [3,4], allowing adolescents with HIV to live well into adulthood [5,6]. Despite this public health success, adolescents with PHIV remain at high risk for a variety of complications, including neurocognitive problems [7,8].

As many as 46% of adolescents with PHIV experience neurocognitive problems [9], despite viral suppression [10,11]. Although both the persistence of HIV and its downstream effects in the central nervous system are thought to play a key role in these complications [12], low socioeconomic status, limited educational opportunities, early life adversity, and other comorbidities are also likely contributing factors [11,13,14]. PHIV typically affects the neurocognitive domains of processing speed and executive functioning [9]. Neurocognitive problems have been associated with poor academic performance, suboptimal ART adherence, increased mental health problems, poor decision-making, and engagement in HIV transmission and other risk behaviors (eg, unprotected sex) [11,15-29].

Early detection of neurocognitive problems can allow for ART regimen adjustments, tailored support approaches, better coping, and earlier intervention [30]. Without timely intervention, these problems may accumulate, limiting adolescents' future independence, employment potential, and quality of life [31]. However, detection of neurocognitive problems is challenging in LMICs for several reasons [32,33]. First, many LMICs, including those in SSA, have a limited number of psychologists and/or neuropsychologists trained to administer, score, and interpret traditional neuropsychological test batteries to measure and diagnose neurocognitive problems [34]. For example, in Uganda, where the current study took place, there are only 0.04 psychologists per 100,000 people, compared with 31.3 per 100,000 in the United States [35,36]. The precise number of neuropsychologists and/or psychologists with specialized neuropsychology training in Uganda is not known.

Second, access to culturally and linguistically appropriate neurocognitive tests is limited. Most tests to date were designed for use by English speakers in high-income countries and, as such, may only be available in English, which may be inappropriate for other cultures and contexts [37-39]. While English is often considered an official language of government and taught in schools in many LMICs, including Uganda, many communities rely on their indigenous languages and local dialects for everyday activities and may not be fully fluent in the officially recognized languages [37,40]. Administering English-language tests in communities that prefer or rely on other languages not only produces invalid test results but also violates ethical practices for psychologists and standardized testing practices [41,42]. Finally, traditional test batteries often require multiple hours to complete—time and resources that overburdened and resource-constrained health care systems in LMICs do not have.

Computerized neurocognitive tests, particularly those that are tablet-based, show promise for use in LMICs and may help make testing more accessible to LMIC populations [43-45]. Compared with traditional tests, computerized tests are highly automated, and many have been designed for administration by a wide variety of personnel who do not have specialized training. Tablet-based tests are also highly portable, and tablets are considerably more affordable than desktop or laptop computers [46,47].

NeuroScreen is a tablet-based battery of neurocognitive tests designed for resource-limited settings [48-50]. It has been validated for use in adult populations with HIV in South Africa [48] and among patients with first-episode psychosis in Uganda [51], as well as with adolescents and young adults with PHIV in Thailand [49] and the United States [39]. This cross-sectional validation study evaluated the construct validity (ie, convergent validity, known-groups validity, and criterion validity), as well as acceptability, of a Luganda-language–adapted *NeuroScreen* for use among adolescents in Uganda living with PHIV. We hypothesized that performance on the *NeuroScreen* battery would be positively correlated with performance on a traditional battery of neurocognitive tests assessing similar domains, that adolescents with PHIV would perform worse than controls on both batteries, and that the 2 batteries would show agreement in the proportion of participants scoring ≤1 SD and ≤2 SD below the global mean.

Methods

NeuroScreen Translation Process From English to Luganda

Prior to data collection, adaptation of the English *NeuroScreen* test instructions and content into Luganda was completed. We

XSL•FO
RenderX

followed a "group consensus" [52] process developed in our laboratory and informed by the International Test Commission [53,54], the American Educational Research Association [41], Nguyen et al [55], and Brislin [56], along with our research team's experience adapting neurocognitive and other measures cross-culturally. Our process began with generating a set of forward translations (English to Luganda) by a professional translator. Next, 4 bilingual (English and Luganda) individuals (1 Master's-level psychologist, 2 research psychometrists, and 1 research assistant) with experience administering traditional neurocognitive tests in Uganda completed blinded, individual back-translations. Back-translators were asked to make notes and identify any Luganda translations that were not easily understood. Then the US-based team reviewed the back-translations to identify differences that could affect the meaning and understandability of the instructions (ie, consistency with the original English and across the back-translations), including any translation issues identified by the translators. A series of 4 meetings with the United States and Ugandan teams was convened to review all translations, with special attention paid to those with identified issues. Final Luganda translations were generated after consensus of the translators was achieved. Some examples of issues addressed were overly technical words and English words without an equivalent in Luganda. For example, the Luganda word for circle is "obukulungwa" but was not readily known by any of the bilingual translators. During the group consensus, the bilingual translators reported that they could infer the word from the context in which it was used (instruction sets for the Trail Making tests) but had not encountered it before. Two of the bilingual translators reported looking up the word in a Luganda dictionary and confirming that it meant circle. Hence, the team decided that an Anglicized version, "esaako," would be much more widely understood by Luganda speakers. Once translations were finalized, audio recordings were made, synced with video instructions, and added to the *NeuroScreen* app.

Participants

In this cross-sectional validation study with a known-groups comparison, participants were 100 Ugandan adolescents (11-20 y): 50 living with PHIV and 50 HIV-negative controls recruited from the same communities as those with PHIV. All participants were recruited from a longitudinal study of cardiovascular health in adolescents with PHIV (K23HD088295; PI: SDF). Participants were included if they were (1) 11 to 20 years old, (2) enrolled in the cardiovascular study, and (3) had documented PHIV or HIV-negative status; participants with PHIV were additionally required to (4) have been on an ART regimen for the last 6 months, and (5) be virally suppressed (<200 copies/mL) at the time of enrollment in the parent study. For the primary correlation of interest (global *z*-scores between the 2 batteries), a sample size of 100 provides ≥80% power to detect a correlation of ≥0.28 in absolute value (a small effect size).

Procedures

This study was carried out at the Joint Clinical Research Centre (JCRC) in Kampala, Uganda, between February 2021 and November 2022. Parents or caregivers of potential participants were approached by study counselors at the JCRC and given information about the study. Trained research assistants collected participants' sociodemographic information before administering the *NeuroScreen* battery on a Samsung Galaxy Tab A 10.5-inch tablet. Participants were given the option to complete *NeuroScreen* in their language of preference, English or Luganda. After completing *NeuroScreen* and taking a short break, participants completed a traditional battery of pencil-and-paper neurocognitive tests and questionnaires.

Ethical Considerations

This study was reviewed and approved by the Uganda National Council for Science and Technology (#HS2266), the JCRC Research Ethics Committee (Uganda), the New York State Psychiatric Institute Institutional Review Board (IRB #8029), and the University Hospitals Cleveland Medical Center IRB (#11-16-18). All procedures were conducted in accordance with the ethical standards of these committees and with the 1964 Declaration of Helsinki and its later amendments. This study was reported according to the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines. The completed STROBE checklist is provided as Checklist 1.

Written informed consent was obtained from all participants aged 18 years and older. For participants younger than 18 years, written informed consent was obtained from a parent or caregiver, and written assent was obtained from the adolescent. Participants and caregivers were informed that participation was voluntary, that they could decline to answer any question, and that they could withdraw from the study at any time without penalty or loss of benefits to which they were otherwise entitled. All study data were deidentified and stored using unique study identification numbers rather than personal identifiers. Data were kept on password-protected, access-restricted secure servers available only to authorized members of the study team.

Participants were compensated 186,000 UGX (approximately US $50 at the time of the study) for their time and travel. The amount was determined in accordance with local norms and approved by the reviewing ethics committees.

Measures

Sociodemographics

Sociodemographic information from caregivers and participants included participants' age, sex, years of education, and household income. Current HIV medical data were obtained from participants' research records and included the most recent viral load and CD4 cell count, as well as the nadir CD4 cell count and years on ART.

Technology Use and NeuroScreen Acceptability

Experience and comfort using digital technologies (ie, desktops and laptops, smartphones with touchscreens, and tablets) were collected with a 12-item questionnaire that asked participants about their experience with computers, smartphones, and tablets (eg, "Have you ever used a smartphone with a touchscreen before?," "How often do you use a smartphone with a touchscreen?," and "How comfortable are you using a smartphone with a touchscreen?"). Responses were either yes/no, frequency-based (eg, every day, 1 - 3 times per week,

XSL•FO
RenderX

or less than once a month), or on a 6-point Likert-type scale (eg, very comfortable to very uncomfortable).

NeuroScreen

NeuroScreen was administered on Samsung Galaxy Tab A 10.5-inch tablets running Android version 10 or 11 by either our Ugandan psychologist (JLG-O) or our research assistant (AN). Both received approximately 2 hours of direct training in the administration of *NeuroScreen*, in addition to a review of the user manual and multiple (~10) practice assessments. *NeuroScreen* was administered in a private and quiet office space and took, on average, 25 minutes to complete. The test battery is embedded in a graphical user interface that allows the examiner to enter participant data and administer the tests. To reduce potential bias, the examiner read standardized test instructions presented on the screen for the verbal learning and memory and verbal working memory tests; embedded instructional videos in the local language were played for the remaining tests. The app automatically cycled through the battery of tests in the same sequence and forced delayed recall of the verbal memory test after a 5-minute delay. After completing all subtests, results were automatically uploaded to a secure server. Each test is automatically scored, thus reducing potential bias. Each test yielded a primary score that was used for analysis. The battery (Table 1) included 5 tests of processing speed, 1 test of executive functioning, 1 test of verbal learning and delayed recall, 1 test of motor speed (finger tapping with dominant and nondominant hands), and 1 test of working memory (number span forward and backward) for a total of 12 scores. For details, see Robbins et al [49].

Table . *NeuroScreen* and traditional test batteries by domain and test.

Domain	*NeuroScreen* battery	Traditional battery
Learning	• Verbal list learning (VLL)	• KABC-II[a]: Atlantis (ATL) [57] • KABC-II: Hand movements (HM) [57]
Memory	• Verbal list learning delayed recall (VLLD)	• KABC-II: Atlantis delayed (ATLD) [57]
Working memory	• Number span forward (NSP-NF) • Number span backward (NSPNB)	• WISC-IV: Digit span forward (DSF) [58] • WISC-IV: Digit span backward (DSB) [58]
Executive functioning	• Trail Making Test 2 (TM2)	• Children's Color Trails Test 2 (CCTT2) [59] • KABC-II: Pattern reasoning (PR) [57] • KABC-II: Rover (RV) [57]

[a]KABC-II: Kaufman Assessment Battery for Children, Second Edition.

Traditional Test Battery

Participants were administered a battery of traditional tests from commonly used neuropsychological test batteries that have been used in research studies with Ugandan adolescents (Table 1) [60-62]. The tests were administered on paper and scored by either a Ugandan Master's-level clinical psychologist (JLG-O) with expertise in neuropsychological assessment or a trained research assistant (AN) supervised by the psychologist. The research assistant received individualized training in the administration and scoring of the traditional battery by our Ugandan psychologist and a postdoctoral clinical psychology fellow with advanced training in clinical neuropsychology (AS). Individualized training included review of test manuals, observation of assessments, practice assessments, and directly supervised assessments (by JLG-O). Only after approval from the Ugandan psychologist was the research assistant allowed to complete assessments without directly observed supervision. To reduce potential bias, only standardized instruction sets were read, and quality assurance methods were conducted throughout the entirety of the study, such that all completed test protocols were reviewed by the US-based postdoctoral fellow (AS). Tests were administered in a private, quiet office space, with test

XSL•FO
RenderX

instructions delivered to children in the local language, and sessions took about 120 to 180 minutes to complete.

The measures assessed 6 neurocognitive domains of functioning: processing speed, working memory, learning, memory, motor speed, and executive functioning. Because we anticipated that most participants would be younger than 18 years and closer to 16 years, we decided to use tests for the younger age range so that all participants would take the same tests. The published upper age limits of the tests are as follows: Kaufman Assessment Battery for Children, Second Edition (KABC-II) [57]—18 years, Children's Color Trails Test (CCTT) [59]—17 years, and Wechsler Intelligence Scales for Children, Fourth Edition (WISC-IV) [58]—16 years. All participants received the same test battery regardless of age; 34 were older than 16 years, including 17 older than 17 years, and 11 older than 18 years. To assess potential ceiling effects among participants older than the upper age limit of these tests, scatterplots were generated and inspected (no evidence of ceiling effects for participants older than the stated age cap for each test was observed).

Data Analysis

Univariate statistics were used to examine participant demographics, technology use, and acceptability. Prior to analyses, sample-based *z*-scores were computed for each test in both batteries; completion-time raw scores for Trail Making 1, 2, and 3, Number Speed, CCTT1, and CCTT2 were reverse-coded so that higher scores indicated better performance. Global *z*-scores were computed by averaging all available *z*-scores for each test in each battery for each participant. To evaluate the convergent validity of *NeuroScreen*, Pearson correlation coefficients (and 95% CI) were computed between the global *z*-scores and each test within each battery. Kendall rank correlation coefficients were also computed for nonnormally distributed tests; however, they did not affect the overall interpretation of the data, and thus, we report only the Pearson correlation coefficients. HIV status served as the grouping variable, and age (in years), sex (male or female), and education (in years) as covariates in adjusted analyses. Known-groups validity was examined with between-HIV group comparisons across each test in each battery, as well as the global *z*-scores, using 2-tailed *t* tests and age-adjusted analyses of covariance. To examine whether prior tablet experience influenced *NeuroScreen* performance, we compared participants who had previously used a tablet with those who had never used a tablet before using *NeuroScreen* across *NeuroScreen* tests and the global *z*-score, with and without adjustment for age and false discovery rate (FDR) correction. Criterion validity was assessed using Cohen κ by comparing the proportion of participants scoring ≤1 SD and ≤2 SD below the global *z*-score of each battery. Between-battery analyses were restricted to participants with complete data on all tests in both batteries (n=95), and missing data were not imputed. To control for multiple comparisons, the FDR [63] was calculated for each battery's between-group comparisons. Data were analyzed using R 4.4.1 (R Core Team, 2024) [64].

Results

Participant Characteristics

One hundred participants were included in the final analysis. Participants' mean age (M_{age}) was 16.6 (SD 1.97; minimum=12.24, maximum=20.80) years; 52% (n=52) were male participants; 92% (n=92) were right-handed. Participants' mean years of education were 8 (SD 2.36) years. PHIV and control participants did not differ significantly on any demographic variables, except for age (*P*=.03), with the PHIV group being almost 1 year older, on average, than the control group (Table 2). Just about two-thirds of participants in each group chose to complete the Luganda version of *NeuroScreen* over the English version. Five participants were excluded from between-battery analyses owing to incomplete data on one or more tests (4 participants were missing one test on the *NeuroScreen* battery, and 1 participant was missing 2 tests on the traditional battery; these were due to errors in administration). Excluded and included participants did not differ in age, sex, education, or HIV status. For between-battery comparisons, a final total sample of 95 was used, which represented complete data on all tests for both batteries. The mean completion time for the *NeuroScreen* battery was 24.69 (SD 2.80) minutes, with the shortest completion time logged as 20 minutes and the longest as 39 minutes.

Technology Use

Table 2 describes the sample's experience using tablet devices. Less than half of the sample (42/97, 43%) had ever used a tablet before using the *NeuroScreen* tablet on the day of their study visit. More controls (25/47, 53%) had used tablets than adolescents with PHIV (17/50, 34%), but this was not statistically significant. Of the 42 participants who reported having used a tablet before, 4 (4%) reported currently owning a tablet. Despite limited tablet use and ownership, the mean ease of use rating for the *NeuroScreen* tablet was in the "very easy" to "easy" range (mean 1.79, SD 0.79). There were no differences between groups on this rating. Just under half the sample (48/97, 49%) had ever used a desktop or laptop computer before, and 91% (88/97) reported having used a smartphone with a touchscreen before. There were no between-group differences in either computer or smartphone use. In an unadjusted analysis examining test performance between those who had ever used a tablet and never used a tablet, participants who had used a tablet before performed significantly better on the visual discrimination 1 and visual discrimination 2 tests (t_{91}=−2.36; P=.02 and t_{95}=−2.09; P=.04, respectively). However, after adjusting for age and FDR, no differences remained significant.

Convergent Validity

Pearson correlation coefficients were computed between the global *z*-scores and individual tests in each battery (Multimedia Appendix 1). The correlation between the 2 global *z*-scores was large and statistically significant (r=0.75; P<.001; 95% CI 0.64-0.83). Correlations between individual tests were generally in the small-to-moderate range, supporting convergent validity between *NeuroScreen* and the traditional battery.

For tests assessing processing speed, correlation coefficients ranged from 0.23 to 0.49. For example, *NeuroScreen* Trail Making 1 was moderately associated with the CCTT1 from the traditional battery (r=0.47; P<.001; 95% CI 0.29-0.61). Similarly, coding and symbol search from the traditional battery

XSL•FO
RenderX

showed moderate correlations with *NeuroScreen* visual discrimination 1 (r=0.33; P=.001; 95% CI 0.14-0.5; and r=0.44; P=.001; 95% CI 0.26-0.59, respectively), visual discrimination 2 (r=0.40; P<.001; 95% CI 0.22-0.55 and r=0.49; P<.001; 95% CI 0.32-0.62, respectively), and number speed (r=0.33; P=.001; 95% CI 0.14-0.49 and r=0.44; P<.001; 95% CI 0.26-0.58, respectively).

For working memory, *NeuroScreen* number span forward was moderately correlated with digit span forward (r=0.34; P=.001; 95% CI 0.15-0.5), as was *NeuroScreen* number span backward with digit span backward (r=0.41; P<.001; 95% CI 0.23-0.56). For learning and memory, *NeuroScreen* verbal learning was modestly correlated with the Atlantis paired-associate learning (r=0.32; P=.001; 95% CI 0.13-0.49), whereas the correlation between delayed memory measures was weaker, with *NeuroScreen* verbal delayed recall showing only a small, nonsignificant association with Atlantis delayed recall (r=0.13; P=.21; 95% CI −0.07 to 0.31). Verbal learning was moderately correlated with hand movements (r=0.36; P<.001; 95% CI 0.18-0.52). For executive function tests, *NeuroScreen* Trail Making 2 and CCTT2 were moderately correlated (r=0.37; P<.001; 95% CI 0.19-0.53). None of the other traditional battery executive function tests correlated with the *NeuroScreen* Trail Making 2 test. The *NeuroScreen* battery did not contain any problem-solving or reasoning tests equivalent to the KABC-II Rover and pattern reasoning subtests; those 2 tests had mostly small correlations with the *NeuroScreen* processing speed and working memory tests. The traditional battery also did not have a pure motor speed test like *NeuroScreen*'s finger tapping, which had small correlations with traditional tests of processing speed, working memory, and learning.

Known-Groups Validity

We examined whether the *NeuroScreen* and traditional tests, and their global *z*-scores, detected performance differences between groups by HIV status. Across both batteries, participants with PHIV showed poorer performance than controls, although not all test-level differences were statistically significant (Multimedia Appendix 2). This pattern was also evident in the global scores: on the traditional battery, participants with PHIV had a significantly lower mean global *z*-score than controls (mean −0.17, SD 0.62 vs mean 0.17, SD 0.51; P=.003; M_{diff} =−0.34; 95% CI −0.57 to −0.12). *NeuroScreen* also showed the same significantly lower mean global *z*-score (mean −0.15, SD 0.60 vs mean 0.12, SD 0.52; P=.02; M_{diff}=−0.27; 95% CI −0.50 to −0.04).

Domain-level findings were broadly consistent across the traditional and *NeuroScreen* batteries (Multimedia Appendix 2). Processing speed showed the strongest cross-battery differentiation, with participants with PHIV performing worse than controls on 4 of 8 measures overall (P=.001 to P=.02). In working memory, both batteries showed the same general pattern of lower performance among participants with PHIV, although no between-group differences were statistically significant. For learning and memory, *NeuroScreen* and traditional measures yielded parallel results, with poorer PHIV performance in unadjusted analyses (learning P=.04 to P=.047; memory P=.04), although these differences were attenuated after adjustment. In motor speed, neither battery differentiated the groups (all P≥.34). In executive functioning, both batteries detected poorer PHIV performance on the trail-making switching-type tests in unadjusted analyses, although only the traditional battery difference was statistically significant (P=.07 and P=.01, respectively). After adjustments, the between-group difference on the traditional test was attenuated.

Criterion Validity

We examined classification agreement between batteries and HIV groups for participants with global *z*-scores ≤−1 SD and ≤−2 SD below the mean. Using the traditional battery, 15 of 95 participants were classified as ≤−1 SD, compared to 11 of 95 on *NeuroScreen*. Across both batteries, more participants living with PHIV than HIV-negative controls were classified as having global *z*-scores ≤−1 SD. The traditional battery classified significantly more participants with PHIV as ≤−1 SD (13 PHIV and 2 controls; χ^2_1=9.86; P=.001) than the *NeuroScreen* battery (7 PHIV and 4 controls; χ^2_1=1.0, P=.32). Agreement between batteries was as follows: 8 participants were classified as ≤−1 SD by both batteries, 7 were identified only by the traditional battery, and 3 only by *NeuroScreen*. This yielded a κ coefficient of 0.56 (95% CI 0.31-0.80).

At the global *z*-score ≤−2 SD below the mean level, the traditional battery classified 2 of 95 participants as ≤−2 SD, compared with 4 of 95 on *NeuroScreen*; neither difference was statistically significant. Agreement between batteries was as follows: 2 participants were classified as ≤−2 SD by both batteries; 2 additional participants were classified as ≤−2 SD by *NeuroScreen* only; no participants were classified as ≤−2 SD only by the traditional battery. This yielded a κ coefficient of 0.66 (95% CI 0.22-1.0).

Discussion

In this study, we adapted *NeuroScreen* for use with English- and Luganda-speaking Ugandan adolescents and examined its construct and criterion validity compared with a widely used traditional test battery. Overall, the findings support the use of *NeuroScreen* as a brief, tablet-based approach for assessing neurocognitive functioning in this population. Global performance on *NeuroScreen* was strongly correlated with global performance on the traditional battery, and adolescents with PHIV performed more poorly than HIV-negative controls on both batteries. Tests assessing similar domains had small to moderate correlations.

Convergent validity was most clearly supported by the strong, statistically significant correlation between the global *z*-scores derived from *NeuroScreen* and the traditional battery (r=0.75). Correlation coefficients between conceptually similar processing speed tests were among the highest (r=0.37-0.48), with conceptually similar tests of attention and working memory having similar correlations (r=0.30-0.47), and a conceptually similar executive functioning test showing a moderate correlation (r=0.34). These findings are encouraging because an exact one-to-one correspondence between computerized and traditional tests is not necessarily expected, even when they are intended to assess similar domains [65,66]. Differences in

XSL•FO
RenderX

modality, response demands, timing parameters, and stimulus format may account for the modest, rather than large, test-level correlations [65-67].

Furthermore, the modest test-level correlations are likely a function of the *NeuroScreen* tests being considerably shorter than the traditional battery tests (eg, coding has a time limit of 120 s vs 45 s for the *NeuroScreen* visual discrimination 2 test, and thus the latter yields fewer scorable responses). Hence, each *NeuroScreen* test comprises fewer items than its traditional counterpart and therefore, by classical test theory, carries less measurement information and lower reliability, meaning briefer tests will correlate more weakly with longer traditional tests even when both assess closely related constructs [68-70]. This is the pattern we observed, and for this reason, the global scores, which aggregate scores across many subtests and thus represent greater length and reliability, are a more appropriate index of convergent validity. This also carries an important implication for *NeuroScreen*. The approximately 25-minute *NeuroScreen* battery shares approximately 56% of the variance with the traditional battery (r=0.75 or r^2=0.56), which requires 120 to 180 minutes to administer (and more time to score and interpret). *NeuroScreen* captures much of the same signal as the traditional battery at a small fraction of the assessment burden—an efficiency especially valuable in low-resource settings.

NeuroScreen was able to distinguish performance between adolescents with PHIV and controls. Adolescents with PHIV had significantly worse global performance on *NeuroScreen* compared with controls. This finding was the same for the traditional battery. Adolescents with PHIV performed worse than controls on all but 2 individual tests and significantly worse on 4 tests in the *NeuroScreen* battery, compared with 6 tests in the traditional battery, and this pattern mostly remained after age adjustment. When adjusting for the FDR on unadjusted comparisons, only 3 of the traditional battery tests remained significant. When adjusting for the FDR on age-adjusted comparisons, only 2 of the traditional battery tests remained significant. Notably, the magnitude of the group differences was similar across batteries, suggesting that *NeuroScreen* was sensitive to the neurocognitive difficulties associated with PHIV in this sample. These findings are consistent with prior work from Uganda and other settings showing that youth with PHIV remain at risk for neurocognitive difficulties despite access to ART [61,62,71]. They also extend prior *NeuroScreen* validation work in PHIV-affected youth and Ugandan clinical populations by demonstrating similar performance with a Luganda-adapted version among Ugandan adolescents [39,49,51].

At the domain level, the most consistent differences between participants with PHIV and controls were observed in processing speed and executive functioning. This pattern is broadly in line with the literature on HIV-associated neurocognitive difficulties in youth, for whom slowed processing speed and executive inefficiencies are among the most commonly reported deficits [9,71,72]. In contrast, differences in learning and memory were significant in unadjusted analyses but were attenuated after age adjustment. Working memory differences were in the expected direction but did not reach statistical significance. These findings suggest that *NeuroScreen* may be especially useful for detecting the domains most consistently affected in PHIV, while also highlighting that not all cognitive domains are equally discriminating in a relatively small sample of virally suppressed youth. Importantly, the absolute differences in mean global *z*-scores between groups were modest, which may reflect the relatively good clinical status of this cohort, all of whom were virally suppressed. Even so, both batteries detected meaningful between-group differences, indicating that subtle but measurable neurocognitive vulnerability persists in this population.

The classification results provide additional support for criterion validity. Both batteries identified more participants with PHIV than controls at ≤1 SD and ≤2 SD below the sample mean global *z*-scores. Between-group differences in classification rates were only statistically significant in the traditional battery at ≤1 SD below the mean threshold. There was a moderate level of agreement between the batteries in their classifications. Given the modest sample size and the small number of participants falling below the classification thresholds, these analyses should be interpreted cautiously. Still, the convergence between the 2 batteries suggests that *NeuroScreen* may have utility not only for continuous assessment of neurocognitive performance but also for identifying youth who may warrant more comprehensive follow-up evaluation.

A major strength of *NeuroScreen* in this context is its feasibility for scale-up. Neurocognitive assessment in many low-resource settings is constrained by shortages of trained specialists, limited availability of culturally and linguistically appropriate tools, and the time burden of traditional batteries. *NeuroScreen* addresses several of these barriers by standardizing administration, automating scoring, and reducing administration time. In its current form, *NeuroScreen* only requires approximately 25 minutes to complete and provides information in line with traditional neuropsychological test batteries, which require considerably more time to complete and score (some batteries can require 2 - 6 h just for administration). This is particularly relevant in Uganda and similar LMIC settings, where specialist neuropsychology resources are scarce. The successful Luganda adaptation also underscores the importance of culturally and linguistically grounded test development. Rather than simply translating instructions literally, the adaptation process aimed to preserve meaning and comprehensibility for local users, which is essential for valid assessment [55].

Acceptability findings further support the promise of *NeuroScreen* for use in Uganda. Although many participants had never previously used a tablet, most reported that the app was easy to use. This is notable because familiarity with digital devices is often raised as a concern when introducing tablet-based assessments in low-resource settings [67,73,74]. In this sample, limited prior tablet experience did not appear to prevent successful completion of, or favorable impressions of, the assessment. These findings suggest that, with appropriate orientation and localized instructions, *NeuroScreen* can be acceptable even among youth with limited exposure to this specific technology platform.

Several limitations should be acknowledged. First, this was a relatively small cross-sectional study, which limited statistical

XSL•FO
RenderX

power, particularly for impairment classification analyses and finer-grained domain comparisons. Second, the traditional battery used as the comparator is not a true gold standard for neurocognitive assessment in this context. As in many LMIC settings, available traditional neuropsychological tests themselves have limitations related to cultural fit, language, and normative data. Accordingly, this study should be understood as evaluating *NeuroScreen* against a commonly used battery of tests rather than against a definitive reference standard. Relatedly, because no published normative data exist for adolescent populations in Uganda for either battery's tests, sample-based *z*-scores were used, which can inflate agreement. Third, because all participants with PHIV were virally suppressed and were recruited from an existing urban research cohort, findings may not generalize to youth with less stable HIV disease, those not engaged in care, or more socioeconomically diverse populations. Fourth, several of the traditional measures were administered to participants who exceeded the tests' published upper age limits (KABC-II, 18 y; CCTT, 17 y; WISC-IV, 16 y). Because we anticipated that most participants would be near 16 years of age and wanted every participant to complete an identical battery, we selected the younger-age forms for the full sample. Administering tests beyond their normed age ranges can affect the validity of age-referenced interpretation and may compress scores near the top of the range, potentially attenuating between-group differences. To assess this, we inspected scatterplots of raw scores against age for each affected test and found no evidence of ceiling effects among older participants. Because our analyses relied on sample-based *z*-scores rather than the tests' published norms, the influence of exceeding the normative age ranges on our findings is likely limited, though it cannot be fully excluded. Fifth, to optimize study workflow, we did not counterbalance the order of battery administration. As such, order, practice, or fatigue effects on the second (traditional) battery cannot be ruled out. Sixth, we note that the data were collected 4 to 5 years ago. Nonetheless, we do not believe this would have much bearing on interpretation of the findings because the study evaluates psychometric properties of the adapted tests, which are not time-sensitive. In addition, the versions of the *NeuroScreen* and the traditional battery tests have not changed. Furthermore, the clinical profile of the virally suppressed Ugandan adolescents with PHIV has remained largely unchanged. Moreover, the shortage of neuropsychology specialists and valid neuropsychological tests for Luganda-speaking populations also remains. Finally, because this study focused on validity and acceptability, additional work is still needed to establish clinical cut-points, longitudinal sensitivity, and predictive utility for functional outcomes such as school performance, medication adherence, and daily functioning.

Despite these limitations, the present findings have important implications. *NeuroScreen* offers a brief, scalable, and locally adapted approach to neurocognitive assessment that showed a similar pattern of group differences to a traditional neuropsychological test battery. In settings where the use of traditional neuropsychological test batteries is not feasible or practical, a tool such as *NeuroScreen* could expand access to screening and help identify youth who may benefit from monitoring, referral, or intervention. Future studies should examine its performance in larger and more diverse samples, assess test-retest reliability and sensitivity to change over time, and determine how best to integrate *NeuroScreen* into routine HIV care for adolescents in SSA.

Acknowledgments

The authors would like to thank the participants and their caregivers who participated in this research. The authors would also like to thank Betty Nyangomo and Mary Nyakato for their assistance in the translation process. The authors used Claude Opus 4.8 to improve the readability of portions of the manuscript. All AI-assisted text was reviewed and edited by the authors, who take full responsibility for the content.

Funding

This work was supported by the National Institutes of Health (K23HD088295 to SDF; R21TW011683 to RNR; R01HD113450 to RNR, SDF, and VM; and P30MH043520). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Data Availability

The data sets generated and analyzed during this study are not publicly available due to privacy and ethical restrictions on participant data, but are available in deidentified form from the corresponding author upon reasonable request, subject to the study's ethics approval and data-sharing agreements.

Abstract

Background: Individuals who are blind or have low vision experience disproportionate burdens in both physical and psychological functioning, and mobile health apps may help address some of these needs. However, their availability, accessibility, and empirical support for this population remain unclear.

Objective: This systematic review aimed to identify mobile health apps relevant to supporting physical and psychological functioning in individuals who are blind or have low vision, summarize the empirical evidence available for these apps, and examine their accessibility and quality.

Methods: We used a multicomponent approach that combined (1) identification of apps through organizational recommendations; (2) a systematic search of the scientific literature, conducted and reported in accordance with PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines; and (3) an exploratory accessibility and app quality appraisal using the Web Content Accessibility Guidelines 2.1 and the Mobile App Development and Assessment Guide.

Results: A total of 19 unique mobile health apps were identified after combining and deduplicating apps identified through organizational recommendations and scientific literature. Fifteen apps were identified through organizational recommendations, and 14 empirical studies evaluating 11 apps were included in the qualitative synthesis. Only a subset of these studies specifically involved blind or low-vision participants; several evaluated apps in broader clinical or general populations where visual impairment status was not reported. The identified apps focused primarily on physical functioning, particularly medication management, glucose monitoring, pharmaceutical information access, and health care access. No apps primarily designed to support psychological functioning in individuals who are blind or have low vision were identified. Of 14 studies, 6 (43%) were rated as being of good methodological quality. The exploratory user-informed accessibility appraisal showed variability across apps: MyPills received the most favorable accessibility profile, with "High" ratings across all 4 Web Content Accessibility Guidelines principles, whereas several organizationally recommended apps received low ratings across most principles. Mobile App Development and Assessment Guide scores ranged from 8/39 to 34/39, with Medisafe scoring highest.

Conclusions: The current landscape of mobile health apps for individuals who are blind or have low vision remains limited, uneven in accessibility and quality, and supported by a limited and heterogeneous evidence base. The absence of identified apps targeting psychological functioning represents a particularly important gap. Improving the development and implementation of mobile health apps for individuals who are blind or have low vision will require more than increasing the number of available apps; it will require apps that are accessible from the outset, rigorously evaluated, and developed with the people they are intended to serve.

Introduction

In 2019, the World Health Organization estimated that at least 2.2 billion people worldwide are blind or have low vision [1], and the number of individuals living with blindness is projected to reach 115 million by 2050. Visual impairment is therefore a major global public health issue with substantial implications for health, functioning, and quality of life [2].

Research consistently shows that individuals who are blind or have low vision report poorer physical and mental health outcomes than their sighted peers [3-6]. For example, a recent review [7] concluded that chronic pain, particularly neuropathic ocular pain and back pain, appears to be common in this population. Visual impairment is also a well-established risk factor for falls and fractures [8,9], which may in turn contribute to loss of independence, permanent disability, and increased mortality, especially in older adults [10]. Mental health outcomes are similarly affected. Adults with visual impairments experience higher rates of depression [11] and anxiety [4] than those with normal vision, and greater severity of visual impairment has also been associated with increased risk of suicidal thoughts and behaviors [12,13].

Despite the elevated risks, access to health care remains limited for individuals with disabilities, including those with visual impairments [14]. Previous research has documented persistent disparities in preventive care, health care usage, and access to appropriate treatment compared with sighted individuals [2,15,16]. For example, although older adults with visual impairments present higher rates of clinically significant depression and anxiety [17], many never receive appropriate treatment [18,19]. Even in settings where accessibility is legally mandated, implementation is inconsistent [20]. Access to effective treatment is further restricted by the limited accessibility of many medical technologies. For example, insulin pumps and other diabetes-related devices often lack basic accessibility features such as voice guidance and accessible instructions [21], despite the relevance of diabetes in this population.

Mobile health apps (ie, software designed for smartphones, tablets, and other portable devices [22]) have emerged as promising tools to support the management of chronic noncommunicable diseases, such as chronic pain [23,24], diabetes [25], hypertension [26], depression [27], and anxiety [28]. For individuals who are blind or have low vision, mobile apps can promote autonomy, enhance communication with health care professionals and peers, and improve personalized care and overall quality of life [29-33]. However, many commercially available apps are developed primarily for commercial rather than clinical purposes and lack rigorous empirical support [34]. Limited involvement of key stakeholders, particularly end users [35], may further contribute to mistrust, privacy concerns, and the dissemination of inaccurate or even potentially harmful information [36,37]. Some reviews and empirical studies have begun to describe the broader landscape of mobile app usability for visually impaired users. For example, Al-Razgan and colleagues [29] conducted a systematic literature review on the usability of mobile apps for people with visual impairments, identifying key themes such as accessibility, assistive technologies, navigation, and interaction design. Their review provides an important overview of the general usability challenges faced by visually impaired users in mobile environments. However, mobile health apps, particularly those intended to support the physical and psychological functioning of individuals who are blind or have low vision, received far less systematic attention.

To our knowledge, no systematic review has specifically examined mobile health apps relevant to individuals who are blind or have low vision with a focus on their potential role in supporting physical and psychological functioning, the empirical evidence supporting their use, and the extent to which such apps meet current accessibility and quality standards. Conducting such a review has important implications for both research and clinical practice: it can help identify promising tools, clarify important gaps in the evidence base, and inform the development and recommendation of apps that are both effective and accessible for this population.

Accordingly, this systematic review addressed three research questions: (1) Which mobile health apps relevant to individuals who are blind or have low vision can be identified through organizational recommendations and the scientific literature? (2) What empirical evidence is available regarding the usability, accessibility, and health-related outcomes of these apps? (3) What do the exploratory user-informed accessibility appraisal and app-quality assessment suggest about the accessibility and quality of the identified apps?

Methods

Procedure

Overview

This study followed a multicomponent review design intended to address complementary dimensions of the same research problem. First, we identified mobile health apps recommended by organizations serving individuals who are blind or have low vision in order to characterize apps currently promoted within this community. Second, we conducted a systematic review of the scientific literature to identify and examine empirical studies evaluating mobile health apps relevant to this population. Apps identified through organizational recommendations and the scientific literature were then combined and deduplicated by app name, developer, intended function, and platform availability to determine the final number of unique apps included in the review. This review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [38] for systematic reviews and meta-analyses and was conducted in accordance with the preregistered protocol in the PROSPERO [39] database (CRD42023448243). No substantive deviations from the protocol occurred; any minor refinements were limited to improvements in reporting clarity and did not affect the scope, eligibility criteria, or analytical approach. All studies were analyzed using a qualitative synthesis approach. Two independent reviewers (CM and JM) assessed study eligibility using a 2-step process that involved initial screening of titles

XSL•FO
RenderX

and abstracts followed by full-text evaluation. Discrepancies were resolved through discussion, and when necessary, a third reviewer was consulted to reach consensus. Third, we carried out an exploratory, user-informed accessibility appraisal of apps that were available for direct review. This final component was not designed as a stand-alone primary study or as a formal usability trial intended for statistical generalization but rather as a complementary appraisal to provide practical insight into how the identified apps could be accessed and experienced by potential users. Accordingly, the accessibility appraisal was intended to contextualize the evidence synthesis by bridging the gap between published descriptions of apps and their real-world accessibility in use. As this review was based exclusively on previously published literature and did not involve the collection of primary data or direct participation of human subjects, approval from an Institutional Review Board (IRB) or Research Ethics Committee was not required.

Identification of Apps Recommended by Organizations Serving Individuals With Visual Impairments

To identify mobile health apps currently recommended to individuals who are blind or have low vision, we conducted a targeted review of websites and digital resources from organizations serving this population. These organizations often act as key sources of information and dissemination channels for assistive technologies and digital tools within the visually impaired community. Organizations from different geographical regions were considered, including international, national, and regional organizations that provide resources and support for individuals with visual impairments. Examples include the American Foundation for the Blind, the Royal National Institute of Blind People, the World Blind Union, the Spanish National Organization for the Blind (ONCE), and Vision Australia. The websites of these organizations were systematically examined to identify mobile health apps intended to support physical and psychological functioning in individuals who are blind or have low vision and those that were recommended or listed as potentially useful for this population. When relevant information was available, we recorded basic descriptive characteristics of each app, including the app name, platform availability (ie, iOS or Android), intended purpose, and any description provided by the recommending organization.

Systematic Search of the Scientific Literature on Mobile Health Apps Intended to Support Physical and Psychological Functioning

To identify empirical studies on mobile health apps intended to support the physical and psychological functioning of individuals who are blind or have low vision, we conducted a systematic search of the scientific literature. The search was performed in 3 major databases: ScienceDirect, PubMed or MEDLINE, and other National Center for Biotechnology Information (NCBI) resources. The search strategy combined terms related to mobile apps and visual impairment. Specifically, the following keywords were used: (“app*” OR “mobile” OR “smartphone”) AND (“visually impaired” OR “visual disability” OR “blind*” OR “low vision” OR “ocular*” OR “eye*”), using asterisks as wild cards to capture variations of each term. A supplementary app-name search was also conducted for apps identified through organizations serving individuals with visual impairments, combined with the same keyword strategy. The initial search was conducted in ScienceDirect, PubMed or MEDLINE, and other NCBI resources and covered records published through December 2025. In April 2026, the search was updated and extended across all 6 databases included in the final review: ScienceDirect, PubMed or MEDLINE, PubMed Central, Scopus, Web of Science, and the ACM Digital Library. All 6 databases were searched from inception through April 2026. Thus, the April 2026 update both extended the final coverage date of the databases included in the initial search and broadened database coverage by adding Scopus, Web of Science, and the ACM Digital Library. The updated search strategy was developed through an iterative refinement process. Initial exploratory searches using broad terms yielded a high proportion of irrelevant records due to the ambiguity of certain keywords. Therefore, search terms were progressively refined by prioritizing more specific descriptors related to mobile apps and visual impairment and by combining these with methodological terms (eg, “evaluation” and “empirical study”) where appropriate. This approach aimed to balance sensitivity and specificity, ensuring adequate coverage while reducing noise. The search was restricted to peer-reviewed journal papers. Gray literature and conference proceedings were not included as primary evidence sources, as the review focused on empirical studies with formal evaluation components to ensure methodological consistency and comparability across studies. The full database-specific search strategies used in the updated search, including complete search strings, Boolean operators, filters, and records retrieved per source, are provided in Multimedia Appendix 1. The supplementary app-name search was intended to identify empirical studies on apps already recommended in practice, while the broader database search aimed to capture additional relevant apps not identified through organizational sources.

To maximize comprehensiveness, we also manually screened the reference lists of eligible papers for additional studies. Studies were included if they met the following criteria: (1) evaluated a mobile app intended as relevant to individuals who are blind or have low vision, because it was designed for this population, recommended by organizations serving this population, or identified in the scientific literature as potentially relevant; (2) reported empirical findings related to the app; (3) were published in a peer-reviewed journal; (4) were available in full text; and (5) were written in English or Spanish. Studies were eligible even when the empirical evaluation was conducted in a broader clinical or general population, provided that the app itself had been identified as relevant to individuals who are blind or have low vision. Data extraction was performed using a structured template developed for this review. Extracted variables included study characteristics (authors, year, country, and design), participant characteristics, app name and purpose, health domain addressed, key accessibility and usability findings, and the main outcomes reported. Study designs were categorized into broader groups (eg, observational and experimental) to facilitate consistent reporting and comparison across heterogeneous studies. The data extraction form used in this review, including all extracted variables, is provided in Multimedia Appendix 2.

XSL•FO
RenderX

Assessment of Methodological Quality and Risk of Bias

Methodological quality and risk of bias were assessed by 2 reviewers (CM and JM) using the version of the National Institutes of Health (NIH) Quality Assessment Tool appropriate to each study design. Discrepancies were discussed and resolved by consensus following guidance from the Cochrane Handbook for Systematic Reviews of Interventions. The final ratings for all included studies were based on this consensus process.

For each study, the NIH criteria were rated as "yes," "no," "cannot determine," or "not applicable," as appropriate. "Cannot determine" was used when insufficient information was available to judge an item, and "not applicable" when a criterion was not relevant to the study design. To obtain an overall indicator of methodological rigor, "yes" responses were scored as 1 point, whereas all other responses ("no," "not reported," "cannot determine," or "not applicable") were scored as 0, and item scores were summed across criteria. Consistent with approaches used in previous systematic reviews [40-42], total scores were categorized as poor (0 - 6), fair (7-10), or good (11-14). For ease of interpretation, the resulting ratings are presented both at the item level and as an overall summary classification.

Exploratory Accessibility and Functionality Appraisal of the Identified Mobile Apps

This appraisal was conceived as an exploratory complement to the review. Consequently, the resulting ratings should be interpreted as illustrative observations derived from participant experiences and consensus discussions rather than as a formal usability study or as independently generalizable evidence. The accessibility and functionality of the identified apps were appraised using the Web Content Accessibility Guidelines (WCAG 2.1, 2018) [43] framework focusing on the 4 POUR principles: (1) Perceivable (ie, information and user interface elements must be easily perceivable by users), (2) Operable (ie, all elements should be fully interactive, free of distracting animations, or gestures that require the use of multiple fingers), (3) Understandable (ie, information and interface functions should be clear and easy to understand), and (4) Robust (ie, apps should be compatible with different devices and operating systems, including features such as adjustable font sizes). In practical terms, the accessibility appraisal examined whether relevant app information and interface elements were perceivable (eg, accessible labels, readable content, and discernible feedback), whether navigation and controls were operable (eg, keyboard or screen-reader accessibility, predictable navigation, and actionable controls), whether content and interaction flows were understandable (eg, clarity of instructions, consistency, and comprehensibility of interface elements), and whether the app appeared robust in its compatibility with assistive technologies and platform accessibility services. Although WCAG was originally developed for web content, its principles have also been applied and adapted to mobile and nonweb software environments in World Wide Web Consortium (W3C) guidance and prior accessibility research [43,44]. Because some WCAG wording is web-oriented, criteria were interpreted in relation to mobile app environments following established W3C guidance for nonweb Information and Communication Technologies and mobile apps. Thus, references to web pages were considered at the level of app screens or views, and accessibility judgments were made in relation to native app interactions and compatibility with mobile assistive technologies. Following this approach, we applied WCAG 2.1 to native mobile apps to assess barriers and facilitators relevant to individuals who are blind or have low vision, particularly those related to screen reader compatibility, interface clarity, navigation, and interaction with core app functions.

To assess the accessibility and functionality of the identified apps, we conducted a user-based appraisal guided by the WCAG 2.1 framework. Four adult volunteers with visual impairments participated in the evaluation (2 blind and 2 with reduced visual acuity). Participants were recruited through convenience sampling based on accessibility and prior experience using mobile assistive technologies. No formal inclusion or exclusion criteria were applied beyond having lived experience of visual impairment and familiarity with smartphone use. Participants were instructed to download, install, and test the core functionalities of each app (eg, setting medication reminders and navigating menus) using the native accessibility features available on their devices. Following individual testing, participants discussed their experiences in a group session and appraised each app in terms of ease of use, clarity of information, compatibility with screen readers or other assistive technologies, and overall performance across the 4 WCAG principles. Based on this process, each app received an overall rating of low, moderate, or high for each WCAG principle. When disagreement occurred, the most stringent rating was retained in order to prioritize barriers encountered by blind users. These ratings therefore reflect a consensus-based synthesis of the participants' practical experience with the apps rather than a formal psychometric assessment, standardized accessibility measurement, or clinical evaluation. No interrater reliability, test-retest reliability, or formal validation procedure was conducted for this exploratory component. A detailed operationalization of WCAG 2.1 principles, including examples, is provided in Multimedia Appendix 3. In addition, we reviewed scientific literature related to the accessibility and functionality of the identified apps to complement the user-based appraisal. Given the small and diagnostically homogeneous sample, this component was intended to enrich the review with real-world end user perspectives rather than to generate generalizable estimates of usability.

App Quality Appraisal Using the Mobile App Development and Assessment Guide

Each identified app was also appraised using the Mobile App Development and Assessment Guide (MAG) [35]. The MAG is a structured framework developed to support the assessment of mobile health apps across multiple domains relevant to quality, including usability, privacy, security, appropriateness, safety, and technology performance. The guide includes 39 items organized into seven categories: (1) Usability, (2) Privacy Policy Information, (3) Privacy Features, (4) Security, (5) Appropriateness and Suitability, (6) Safety, and (7) Technology Performance [34]. Two independent researchers (CM and PLl-V) reviewed each app against the 39 MAG criteria. Each item was rated as "yes" when the criterion was met, "no" when

XSL•FO
RenderX

it was not met, and "not applicable" when the criterion could not reasonably be assessed for a given app. Agreement between reviewers was approximately 90% before consensus discussions. Disagreements were generally minor and primarily reflected different interpretations of individual MAG criteria. These discrepancies were resolved through discussion and consensus review before final scores were assigned. The full list of MAG criteria used in the evaluation is presented in Table 1. In addition to the item-level appraisal, an overall summary score was calculated for each app based on the number of MAG criteria met, in order to facilitate comparison across apps. Because the MAG does not provide predefined cutoff points for interpreting total scores, descriptive score bands were created for this review. Apps meeting approximately two-thirds or more of the MAG criteria were classified as higher app quality (≥27/39), apps meeting approximately one-half to less than two-thirds of the criteria were classified as moderate app quality (20-26/39), and apps meeting fewer than one-half of the criteria were classified as lower app quality (≤19/39). These categories were used only to aid interpretation of the descriptive MAG scores and should not be interpreted as validated MAG thresholds.

Table . Mobile App Development and Assessment Guide (MAG) criteria used to appraise the quality of mobile health apps for individuals who are blind or have low vision.

Item	Statement	MAG category
1	The app was tested by potential users before being made available to the public.	Usability
2	It is easy to use.	Usability
3	The app features are adapted to the purposes of the app.	Usability
4	Functionality is adjusted to the targeted user.	Usability
5	The app is designed to be accessible for people with physical impairments.	Usability
6	The app uses lay language that can be easily understood by the targeted user.	Usability
7	The user can easily access all resources and features.	Usability
8	The app provides information about the terms and conditions for the use of the app.	Privacy Policy Information
9	The app provides information about privacy policies.	Privacy Policy Information
10	The app provides information about commercial agreements with third parties or the absence of them.	Privacy Policy Information
11	The app informs users if their data must be transferred to third parties for the app to operate.	Privacy Policy Information
12	The app indicates a recommended user age based on its content.	Privacy Policy Information
13	The app includes a simple and understandable version of the terms and conditions of use, and privacy policies.	Privacy Policy Information
14	The app gives a warning when an update influences sensitive data.	Privacy Features
15	The app provides the option to only collect user data that are essential for the app to operate.	Privacy Features
16	The app guarantees users' rights on stored personal data.	Privacy Features
17	The app provides the user with the option to refuse the transfer of data to third parties.	Privacy Features
18	The app requires the user to give her or his consent to the terms and conditions of use and privacy policies.	Privacy Features
19	The app notifies the user when other resources on the mobile device, such as her or his accounts or social network profiles, are accessed.	Privacy Features
20	The app guarantees the user’s privacy.	Privacy Features
21	The app offers to delete the user’s data at any time.	Privacy Features
22	The app informs the user about the security measures in place.	Security
23	The app includes password management mechanisms.	Security
24	The authorization and authentication mechanisms work correctly.	Security
25	The app validates the user’s identity to access confidential data.	Security

XSL•FO
RenderX

Item	Statement	MAG category
26	The app informs the user when it detects and identifies cybersecurity vulnerabilities, possible threats, and the risk of being exploited that may affect the data.	Security
27	The app informs the user that when a third-party component is updated, the updated version is inspected, and the risks are evaluated.	Security
28	The benefits and advantages of using the app are explained.	Appropriateness and Suitability
29	Experts have participated in the development of the app.	Appropriateness and Suitability
30	The app informs the user that it is based on scientific findings.	Appropriateness and Suitability
31	The app informs the user that it is developed in accordance with ethical principles and values.	Appropriateness and Suitability
32	The possible health risks for the user are identified.	Safety
33	The app complies with regulatory standards as a medical device.	Safety
34	The user is warned when adverse events are identified.	Safety
35	The app recommends that users always consult a specialist if they have questions, or it warns users that the app is not meant to replace the services provided by a health professional.	Safety
36	The app works correctly.	Technology Performance
37	Functions are correctly retrieved after events external to the app occur.	Technology Performance
38	The app uses mobile device resources efficiently (eg, battery, CPU, memory, data, network, etc), giving it a level of performance high enough not to interfere with the user's experience.	Technology Performance
39	The app has a data recovery system in case of loss.	Technology Performance

Results

Overview

The results are organized according to the 3 research questions and the corresponding methodological components of the study. We first describe the mobile health apps identified through organizational recommendations and the scientific literature. We then summarize the empirical evidence available for these apps, including an assessment of the risk of bias and quality of these studies. Finally, we present the exploratory accessibility and functionality appraisal and the app quality assessment of the identified apps.

Mobile Health Apps Identified Through Organizational Recommendations

After combining and deduplicating apps identified through organizational recommendations and the scientific literature, 19 unique mobile health apps were included in the review. Fifteen apps were identified through organizational recommendations and 11 were evaluated in the empirical studies included in the qualitative synthesis. These counts should not be summed because 7 apps were identified through both sources, 8 were identified only through organizational recommendations, and 4 were identified only through empirical studies. Apps were counted as unique when they represented distinct apps after comparison by app name, developer, intended function, and platform availability. Among the 15 apps identified through organizational recommendations, all were freely available, and most (14/15, 93%) were compatible with both iOS and Android platforms. Across the 19 unique apps included in the review, none specifically targeted psychological functioning or mental health concerns. Six apps (ie, Medisafe, MyFitnessPal, SACYL Cita Previa, Salud Informa, SCSalud, and SESCAM) were recommended by both Fundación ONCE and the American Foundation for the Blind, whereas the remaining apps were endorsed by a single organization.

Apps identified only through the scientific literature were retained as additional unique apps when they represented distinct mobile apps not already captured through organizational recommendations. Across the 15 apps identified through

XSL•FO
RenderX

organizational recommendations, 2 broad functional categories were identified. First, several apps supported health self-management or health-related information access, including medication scheduling, medication information retrieval, glucose monitoring, nutrition tracking, or physical activity support. These included apps with medication scheduling and reminders (eg, Medisafe and Alarma de Medicamentos), medication information access or voice-based output (eg, ScripTalk and Medicamento Accesible Plus), glucose monitoring or diabetes self-management functions (eg, Glucose Buddy Diabetes Tracker, OneTouch Reveal, DiabetesPal, and FreeStyle LibreLink), and nutrition or weight management support (eg, MyFitnessPal). Second, several apps primarily supported health care access or administrative functions, such as appointment scheduling, prescription management, or integration with regional public health systems (eg, SACYL Cita Previa, Salud Informa, SCSalud, SESCAM, GVA + Salut and Astursalud Cita Previa). These apps are linked to specific Spanish regional public health systems and are generally restricted to individuals receiving care within those systems. They are therefore not broadly available or directly transferable to users in other national or regional health care contexts. These administrative apps were explicitly identified through the organizational recommendation component and may provide meaningful access to appointments, prescriptions, health records, and other services within their intended local settings. However, they should be interpreted as a separate category of locally contextualized health care access tools rather than as equivalent to internationally available clinical self-management apps, such as medication management, glucose monitoring, or health information tools. The main features and functional categories of these apps are summarized in Table 2.

XSL•FO
RenderX

Table . Main features of mobile health apps identified through organizational recommendations for individuals who are blind or have low vision.

Mobile app	Functional category[a]	Organization	Operating system	Developer	Languages	Key features	Price	Downloads, n
Alarma de Medicamentos	Medication management	Fundación ONCE	Android/iOS	Aplicativos legais LTDA-ME	English, Spanish, Portuguese, French, German, Italian, Russian, Korean, Turkish, and others	Customizable medication reminders and dosage tracking	Free with in-app purchases	>1 million
Astursalud Cita Previa	Health care access or administrative	Fundación ONCE	Android	Gobierno del Principado de Asturias	Spanish	Manage primary care appointments within the Asturias (Spain) regional public health system	Free	76,000
DiabetesPal	Diabetes self-management	American Foundation for the Blind	Android/iOS	Pascal Freiburghaus	English and German	Diabetes management: track glucose, insulin, and meals; sync across devices via iCloud, Dropbox, or WebDAV	Free to download with in-app purchases	>50,000 (Android)
FreeStyle LibreLink	Glucose monitoring	Fundación ONCE	Android/iOS	Abbott Diabetes Care Inc	Multilingual (includes English, Spanish, French, Italian, and more)	Glucose monitoring with sensor technology; provides historical trends; compatible with LibreView platform	Free to download with in-app purchases	>1 million
Glucose Buddy Diabetes Tracker	Diabetes self-management	American Foundation for the Blind	Android/iOS	Azumio Inc	English	Logs blood glucose, meals, and medications; integrates with Apple Health and Dexcom devices; provides detailed reports and optional coaching	Free with in-app purchases	>1 million
GVA + Salut	Health care access or administrative	Fundación ONCE	Android/iOS	Generalitat Valenciana	Spanish and Catalan from València	Appointment scheduling, medical records, prescriptions, telemedicine, and access to services within the Valencian (Spain) regional public health system	Free	2.4 million

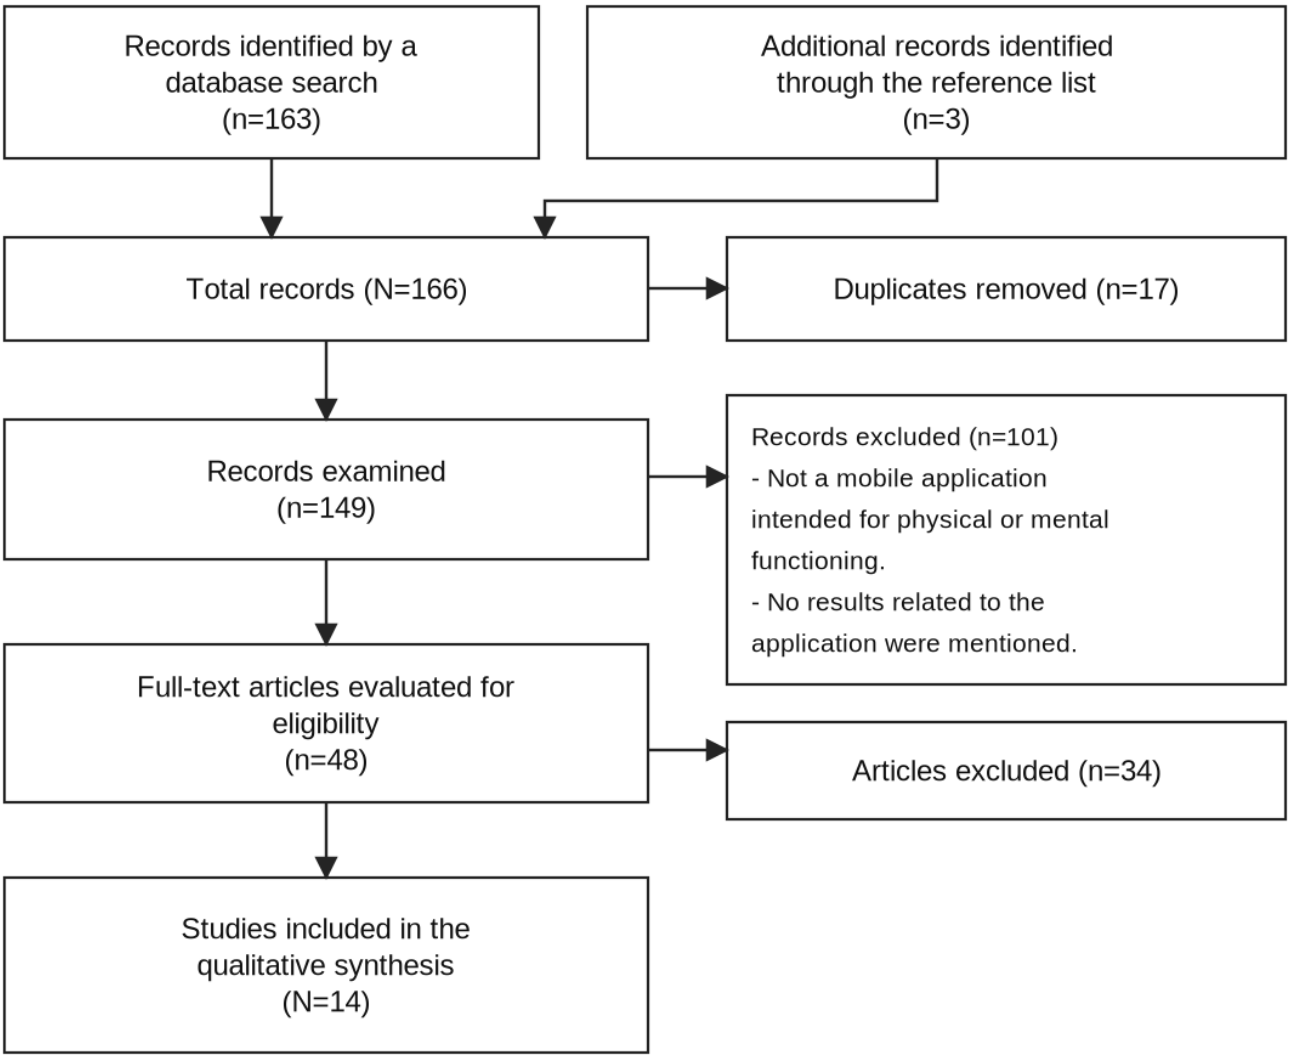
[a]Functional categories distinguish apps primarily intended for health self-management or health-related information access from apps primarily intended to support health care access or administrative functions.

[b]RFID: radio frequency identification.



Studies on Health-Related Apps in Scientific Databases

The database search was conducted in 2 phases. The initial search covered records published through December 2025 in ScienceDirect, PubMed or MEDLINE, and other NCBI resources. In April 2026, the search was updated across these 3 databases and expanded to include Scopus, Web of Science, and the ACM Digital Library; all 6 databases were searched from inception through April 2026. Across these database searches, 163 records were identified. In addition, 3 papers were identified through manual reference screening, yielding a total of 166 records. After removing 17 duplicates, 149 titles and abstracts of papers were screened. Of these, 101 were excluded, leaving 48 papers for full-text review. Following eligibility assessment, 14 studies were included in the qualitative synthesis.

An additional expanded search was also conducted across 6 databases to further examine the coverage of the search strategy: ScienceDirect, PubMed or MEDLINE, PubMed Central, Scopus, Web of Science, and the ACM Digital Library. This expanded search retrieved 1371 records: ScienceDirect (n=222), PubMed or MEDLINE (n=22), PubMed Central (n=54), Scopus (n=579), Web of Science (n=158), and ACM Digital Library (n=336). After duplicate removal and initial screening, 40 papers were selected for further review. Four papers underwent full-text eligibility assessment; however, none met the inclusion criteria. Therefore, the expanded search did not change the final number of included studies. Figure 1 presents the PRISMA flow diagram illustrating the paper selection process.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart illustrating the main study selection process for health-related mobile apps targeting individuals who are blind or have low vision.

The 14 empirical studies examined 11 different mobile health apps identified as relevant to individuals who are blind or have low vision, most often in the context of medication management, diabetes, hypertension, nutrition, or physical activity. However, the population focus of the evidence varied. Some studies specifically involved participants who were blind or had low vision, whereas others evaluated apps recommended for, or potentially relevant to, blind and low-vision users but were conducted in broader clinical or general populations where visual impairment status was not reported. Not all apps recommended by organizations had corresponding scientific evidence, and conversely, not all apps identified in the scientific literature were endorsed by organizations.

These studies used a range of methodologies: cross-sectional designs (6/14, 42%), observational studies (6/14, 42%), and randomized clinical trials (2/14, 14%). Most studies were conducted in the United States (6/14, 42%). Table 3 provides an overview of the 14 studies and the 11 apps evaluated. Because the included studies differed substantially in population focus and outcome type, Table 3 distinguishes between studies involving blind or low-vision participants and studies conducted in broader clinical or general populations where visual impairment status was not reported, and between studies evaluating objective or clinical outcomes and those focused primarily on usability, feasibility, satisfaction, or accessibility-related outcomes. Most of the identified apps were developed specifically to support medication management and access to pharmaceutical information. Despite geographic diversity, several core features were common: (1) voice output for medication identification and instructions; (2) barcode or Global Trade Item Number scanning to recognize medication packaging; (3) accessible search interfaces, usable by text, voice, or image; and (4) reminder systems for dosing and medication refills. These apps were primarily developed for Android platforms and followed user-centered design principles. Many included adjustable user interfaces (eg, text size, spoken descriptions, and voice navigation). Overall, the evidence was heterogeneous in both population focus and outcome type. Studies involving blind or low-vision participants primarily reported findings related to usability, feasibility, medication information access, perceived autonomy, or satisfaction with apps such as ScripTalk, MyPills, FarmaceuticApp, and Ru Tan Ya [5,44,45]. Studies conducted in broader clinical or general populations reported more objective or large-scale outcomes, including medication adherence and blood pressure control for Medisafe [5,46], glycemic metrics for FreeStyle LibreLink [47] and OneTouch Reveal [48,49], weight management behavior

XSL•FO
RenderX

for MyFitnessPal [50], and dietary assessment accuracy for MyFitnessPal [51]. However, findings from broader populations should be interpreted as indirectly relevant to blind and low-vision users unless visual impairment status was specifically assessed. In addition, some barriers were noted. For example, the study of Medicamento Accesible Plus highlighted low digital literacy among older adults as a barrier to effective app use [52].

Table . Overview of empirical studies identified on mobile health apps identified as relevant to individuals who are blind or have low vision by population relevance and outcome type in chronological order of publication.

Authors (year), country	Purposes of the study	Apps	Principal functions	Population relevance to blind or low-vision users[a]	Languages	Sample of study	Type of study	Technical characteristics	Outcome type	Results
Spektor et al (2015) [53], United States	Evaluate effectiveness of ScripTalk for reading prescription labels	ScripTalk	Reads prescription labels aloud	Direct evidence: BLV[b]-specific sample	English	12 veterans with visual impairments	Field study	Allows iOS devices with Near Field Communication capability to read ScripTalk Talking Labels.	Medication access and adherence-related outcome	Improved treatment adherence and independence in medication use
Bee et al (2016) [54], Singapore	To evaluate the app for insulin use in insulin-naive patients with type 2 diabetes	DiabetesPal	Insulin adjustment based on glycemic goals	Indirect evidence: broader clinical population; BLV status not reported	English	62 participants (32 intervention, 30 control); type 2 adult patients with diabetes	Pilot randomized clinical trial	Diabetes data recording (eg, glucose, insulin, medication, blood pressure, etc); graph generation	Insulin titration feasibility and safety	Safe and feasible for insulin titration; no severe hypoglycemia recorded
Morawski et al (2018) [46], United States	To evaluate Medisafe's impact on antihypertensive adherence and blood pressure control	Medisafe	Medication reminders, adherence reports, and caregiver support	Indirect evidence: broader clinical population; BLV status not reported	17 languages, including Spanish, English, Arabic, Danish, Dutch, Finnish, French, German, Hebrew, Italian, Japanese, Korean, Portuguese, Russian, Simplified Chinese, and Turkish	412 adults with uncontrolled hypertension	Randomized clinical trial	Adherence tracking; MedFriend support; multicondition tracking	Medication adherence and blood pressure control	Improved adherence significantly compared with the control group
González Oñate et al (2018) [52], Spain	Evaluate accessibility of medication information for older adults	Medicamento Accesible Plus	Search and read medicine information	Indirect evidence: general older adult population; BLV status not reported	Spanish	Older adults in Spain	Descriptive study	Barcode scanning; health database access	Accessibility and digital literacy	Identified digital divide, highlighting the need for promoting digital literacy

Authors (year), country	Purposes of the study	Apps	Principal functions	Population relevance to blind or low-vision users[a]	Languages	Sample of study	Type of study	Technical characteristics	Outcome type	Results
Choi et al (2025) [51], United States	Develop an accessible conversational mHealth app (Personalized and Conversational Health Agent) to support physical activity in blind and low-vision individuals	Personalized and Conversational Health Agent	Personalized and Conversational Health Agent is a conversational, voice-based health assistant that provides personalized recommendations for physical activity, enables self-monitoring of health metrics (steps and heart rate), and facilitates interactive communication via a voice user interface	Direct evidence: BLV-specific expert evaluation	English with voice-based natural language interaction (ie, via a conversational agent using a large language model)	Two blind accessibility experts evaluated the prototype	Design and development study with qualitative expert evaluation	Uses iOS with large language model integration; voice user interface; multimodal feedback (audio and haptic via Apple Watch); uses physical activity assessment and activity guidelines for Americans to provide physical activity recommendations via an algorithm	Prototype accessibility and expert evaluation	Successful development of a functional prototype with accessible user interface, effective voice interaction, and multimodal feedback; includes 2 experts to test the prototype; limitations identified included response latency, a lack of personalized physical activity feedback, and the need for clearer goal-setting explanations

[a]"Direct evidence" refers to studies that specifically included blind or low-vision participants or expert evaluators. "Mixed evidence" refers to studies including both blind or low-vision and sighted participants. "Indirect evidence" refers to studies evaluating apps identified as relevant to blind or low-vision users but conducted in broader clinical or general populations where visual impairment status was not reported.

[b]BLV: blind or low vision.

[c]RFID: radio frequency identification.

[d]GTIN: Global Trade Item Number.

Assessment of Bias and Quality of Evidence

The interrater reliability in the assessment of methodological quality was high, with 98% agreement between reviewers across all included studies. This high level of agreement reflects the use of a structured appraisal framework with clearly defined criteria, as well as prior calibration between reviewers before the formal assessment. Minor discrepancies, mainly due to different interpretations of the criteria, were resolved through discussion, without the need to involve a third reviewer. A considerable proportion of the studies included in the review presented a moderate or high risk of bias, and out of 14 studies, only 6 (42%) met the criteria for good methodological quality: DiabetesPal [49,54,55], Medisafe [52], MyFitnessPal [50,51], FreeStyle LibreLink [47], and OneTouch Reveal [48]. Most papers reported a clear objective, defined population, and inclusion and exclusion criteria [47,48,56]. However, many did not report participation rates or whether assessors were blinded [45,52]. Table 4 provides a summary of this information. Table 4 should be interpreted as a structured overview of methodological quality across NIH criteria. The overall quality rating reflects the number of criteria met, whereas "Cannot determine" indicates insufficient information to judge an item and "Not applicable" indicates that the criterion was not relevant to the study design.

[a]These items are as follows: 1=study objectives stated, 2=study population defined, 3=eligible participation rate (at least 50%), 4=participant selection and inclusion and exclusion criteria uniformity, 5=sample size sufficient and/or described, 6=exposure measured prior to outcome, 7=sufficient time frame for association between exposure and outcome, 8=inclusion exposure level, 9=exposure measures valid and reliable, 10=multiple exposure measurements, 11=outcome measures valid and reliable, 12=outcome assessors blinded, 13=Loss to follow-up postbaseline (20% or less), and 14=confounders measured and adjusted between exposure and outcome.

[b]Quality ratings were derived using the National Institutes of Health Quality Assessment Tool. Overall ratings were based on the total number of criteria met: poor=0 - 6 “Yes” responses, fair=7 - 10 “Yes” responses, and good=11 - 14 “Yes” responses.

[c]CD: cannot determine (insufficient information available to judge the criterion).

[d]NA: not applicable (criterion not relevant to the study design).

Accessibility, Functionality, and Quality of the Identified Mobile Apps

We conducted an exploratory user-informed accessibility appraisal of the identified apps using the WCAG 2.1 principles: Perceivable, Operable, Understandable, and Robust. These ratings should be interpreted as illustrative user-informed observations rather than as formal accessibility certification, psychometric assessment, or standardized measurement outcomes. The appraisal suggested variability in accessibility across the apps. Within this exploratory user-informed appraisal, MyPills received the most favorable accessibility profile, obtaining “High” ratings across all 4 WCAG 2.1 [43] principles. Participants highlighted its compatibility with screen readers, clear instructions, and reliable performance across devices. In contrast, 6 apps (ie, Astursalud Cita Previa, Glucose Buddy Diabetes Tracker, SESCAM, SCSalud, SACYL Cita Previa, and MyFitnessPal) received “Low” ratings on most or all WCAG principles within this exploratory appraisal. Common issues included poor support for assistive technologies, visually cluttered interfaces without alternatives, and navigation challenges for screen reader users. Examples of accessibility barriers identified during the appraisal included unlabeled controls, insufficient clarity of instructions, inconsistent navigation flows, and limited compatibility with screen-reader interaction. Conversely, apps with clearer menu structures, accessible labeling, and more predictable navigation were judged more favorably. Of the mobile apps identified, 2 (ie, FarmaceuticApp and Ru Tan Ya) could not be downloaded or assessed because they were not available for download in the app stores at the time of assessment. Accessibility ratings of the remaining apps are summarized in Table 5.

XSL•FO
RenderX

Table . Exploratory user-informed accessibility appraisal of mobile apps for users who are blind or have low vision based on the WCAG[a] 2.1 principles[b].

Name of app	Principle 1: Perceivable	Principle 2: Operable	Principle 3: Understandable	Principle 4: Robust
Alarma de Medicamentos	High	High	High	Moderate
Astursalud Cita Previa	Low	Low	Low	Low
DiabetesPal	Moderate	Moderate	Moderate	Low
FreeStyle LibreLink	Moderate	Moderate	Moderate	Low
Glucose Buddy Diabetes Tracker	Low	Moderate	Low	Low
GVA + Salut	Moderate	Moderate	Moderate	Low
Medicamento Accesible Plus	Moderate	Moderate	Moderate	Low
Medisafe	High	High	High	Moderate
MyFitnessPal	Low	Moderate	Low	Low
MyPills	High	High	High	High

Salud Informa	Moderate	Low	Moderate	Low
SCSalud	Low	Low	Low	Low
SESCAM	Low	Low	Low	Low
ScripTalk	High	High	High	Moderate

[a]WCAG: Web Content Accessibility Guidelines.

[b]Ratings were derived from an exploratory user-informed appraisal involving 4 participants (2 blind and 2 with low vision) and should not be interpreted as formal accessibility certification, psychometric assessment, or standardized measurement outcomes.

App quality was assessed using the MAG [34], which includes 39 criteria covering usability, privacy, security, safety, appropriateness, and technology performance. The appraisal showed substantial variability across apps. Medisafe scored highest, meeting 34 of 39 criteria, whereas SACYL Cita Previa scored lowest, meeting 8 of the 39 criteria. Table 6 presents a summary of the MAG total score and the descriptive score band assigned to each app for this review. Higher total scores indicate that a greater number of quality criteria were met, whereas lower scores reflect more limited compliance across MAG domains. The complete item-level MAG appraisal is provided in Multimedia Appendix 4.

XSL•FO
RenderX

Table . Summary of app-quality appraisal using the Mobile App Development and Assessment Guide (MAG).

App	MAG total score of 39, n[a]	Descriptive MAG-based interpretation[b]
Medisafe	34	Higher app quality
Medicamento Accesible Plus	33	Higher app quality
ScripTalk	32	Higher app quality
OneTouch Reveal	31	Higher app quality
FreeStyle LibreLink	29	Higher app quality
Glucose Buddy Diabetes Tracker	29	Higher app quality
MyFitnessPal	28	Higher app quality
MyPills	27	Higher app quality
Salud Informa	25	Moderate app quality
DiabetesPal	24	Moderate app quality
GVA + Salut	22	Moderate app quality
SCSalud	18	Lower app quality
SESCAM	18	Lower app quality
Astursalud Cita Previa	16	Lower app quality
Alarma de Medicamentos	13	Lower app quality
Personalized Conversational Health Agent	12	Lower app quality
SACYL Cita Previa	8/39	Lower app quality

[a]The MAG includes 39 criteria. Higher scores indicate that a greater number of app-quality criteria were met.

[b]Descriptive score bands were created for this review because the MAG does not provide predefined cutoff points for interpreting total scores: higher app quality ≥27/39 criteria met, moderate app quality 20-26/39 criteria met, and lower app quality ≤19/39 criteria met. These categories were used only to aid interpretation of the descriptive MAG scores and should not be interpreted as validated MAG thresholds. The full item-level MAG appraisal is provided in Multimedia Appendix 4.

Discussion

Principal Findings

This systematic review examined the current landscape of mobile health apps intended to support the physical and psychological functioning of individuals who are blind or have low vision. Overall, the findings suggest that this field remains limited in scope, uneven in accessibility and quality, and only partially supported by empirical evidence.

Three main findings emerged. First, the number of identified apps was small, and only a subset had been evaluated in peer-reviewed studies. Second, the available apps focused primarily on physical functioning, particularly medication management and health data tracking, whereas no apps specifically targeting psychological functioning were identified. Third, accessibility and app quality varied considerably, with only a small number of apps performing well across both WCAG and MAG criteria. These findings are broadly consistent with a recent systematic review on the usability of mobile apps for individuals with visual impairments [29]. Although that review did not focus specifically on health-related apps or on physical and psychological functioning, it similarly concluded that the usability of mobile apps for visually impaired users remains limited due to device-related barriers (eg, camera-based interfaces) and user interaction challenges (eg, difficulties interpreting graphical user interfaces) [29].

With respect to the first research question, the apps identified through organizational recommendations, and the systematic search of scientific literature reflected a relatively narrow functional landscape. Most supported medication use, medication information access, glucose monitoring, nutrition tracking, or physical activity support. A separate subset of apps primarily supported health care access or administrative functions, such as appointment scheduling, prescription management, or access to regional health system information. These latter tools may be useful for navigating health care services, particularly in local contexts, but they are functionally distinct from clinical self-management apps such as medication management, glucose monitoring, nutrition tracking, or physical activity tools. Overall, the identified apps represent a restricted subset of the possible ways in which mobile health apps might support functioning in individuals who are blind or have low vision. As a result, they do not reflect a broader conceptualization of functioning that includes psychological well-being, self-efficacy, autonomy, and participation in daily life.

Importantly, the characterization of this landscape as limited should not be understood as a simple consequence of the number of apps identified or of the inclusion of geographically restricted administrative tools. Rather, it reflects the narrow range of functions addressed across the identified apps, the limited number supported by population-specific empirical evidence,

XSL•FO
RenderX

the variability observed in accessibility and app quality, and the absence of apps primarily addressing psychological functioning.

A particularly important finding was the absence of apps specifically targeting psychological functioning. This should be interpreted cautiously, as it reflects an absence of identified apps rather than definitive evidence that none exists. Some apps may include psychological or mental health–related components; however, within the scope of this review, we did not identify apps primarily designed for, or empirically evaluated in, blind and low-vision populations with a specific focus on psychological or mental health functioning. Nonetheless, this gap is clinically meaningful given the elevated burden of depression, anxiety, and psychological distress in individuals who are blind or have low vision [19]. This observation is consistent with Inal and colleagues [57], who reviewed 42 usability studies of mobile mental health technologies and found that none included users with visual impairments. Taken together, these findings suggest that psychological functioning remains insufficiently addressed in both app development and research for this population. By contrast, app-based interventions addressing pain-related symptoms and quality of life have been developed for other chronic pain populations. For example, Fibroline incorporates a self-administered cognitive behavioral intervention designed for young people with fibromyalgia or chronic widespread pain, illustrating how psychological and symptom management components can be integrated into a mobile health app outside the context of blindness and low vision [24,58].

With respect to the second research question, the empirical evidence base was limited in both size and scope. In this review, "evidence" refers to the existence of empirical studies examining an app and should not be interpreted as formal validation in a psychometric, regulatory, or certification sense. Only a minority of identified apps had been examined in empirical studies, and the methodological quality of those studies was variable. Importantly, the available evidence differed in its relevance to blind and low-vision users and in the type of outcomes assessed. Some studies directly involved participants who were blind or had low vision, whereas others evaluated apps recommended for this population but did so in broader clinical or general populations where visual impairment status was not reported. Therefore, evidence of effectiveness or usability in general populations should be interpreted as indirectly relevant rather than as population-specific evidence for blind and low-vision users. Importantly, the available evidence also differed according to the type of outcomes that were assessed. Some studies reported objective or clinical outcomes, including medication adherence and blood pressure control, glucose metrics, weight management behavior, or dietary assessment accuracy. Other studies focused primarily on usability, feasibility, acceptability, satisfaction, medication information access, or perceived usefulness. Consequently, the current evidence base is better understood as comprising 2 complementary forms of evidence: studies evaluating objective or clinical outcomes, predominantly conducted in broader populations, and studies examining usability, accessibility, or user experience, more commonly conducted with participants who were blind or had low vision. This distinction is important because the existence of an empirical study does not necessarily imply demonstrated clinical effectiveness, and findings from broader populations should not be interpreted as direct evidence of effectiveness, accessibility, or usability for blind and low-vision users. Studies conducted in broader clinical or general populations examined objective or clinical outcomes for Medisafe [46], including medication adherence and blood pressure control; FreeStyle LibreLink [56] and OneTouch Reveal [47,48], including glycemic metrics; and MyFitnessPal [49,55], including weight management behavior and dietary assessment accuracy. By contrast, studies involving blind or low-vision participants more commonly examined usability, feasibility, medication information access, satisfaction, perceived autonomy, or prototype accessibility for apps such as ScripTalk [53], MyPills [44], FarmaceuticApp [5], Ru Tan Ya [45], and PCHA [51]. Accordingly, the literature provides some evidence of clinical or behavioral benefit for selected apps in broader populations and some direct evidence of usability or perceived value among blind or low-vision users but very limited evidence combining population-specific evaluation with objective health-related outcomes. The review also identified only partial overlap between apps recommended by organizations and apps supported by empirical evidence. That is to say, several apps endorsed by organizations lacked corresponding scientific evaluation, whereas some apps described in the literature were not recommended by organizations. This discrepancy is important because organizational recommendations may shape what users, families, and clinicians perceive as credible or useful. The findings therefore highlight the need for closer alignment between research, practice, and dissemination processes so that recommended tools are not only accessible but also supported by evidence.

With respect to the third research question, accessibility and app quality were inconsistent across the identified apps. Only a small number of apps appeared to perform well across the exploratory WCAG-informed appraisal and the MAG assessment, whereas others showed substantial limitations. In the exploratory user-informed appraisal, some apps endorsed by organizations appeared to present potential accessibility barriers, including unlabeled graphical elements, limited screen reader compatibility, and complex navigation structures. These observations should be interpreted cautiously because they were derived from a small exploratory appraisal rather than from a formal accessibility validation study. Nevertheless, they are consistent with previous work in accessibility, human-computer interaction, and assistive technology, which has highlighted persistent problems related to interface complexity, visually dependent interaction models, and inadequate compatibility with assistive tools [29,59-61]. Our findings extend that literature by showing that these barriers remain highly relevant even in apps with apparent health value or organizational endorsement.

The user-informed accessibility appraisal also suggests that technical accessibility alone may not be sufficient to ensure meaningful use. Even when apps were theoretically compatible with assistive features, their practical value could still be limited by poor onboarding, inadequate support, unfamiliar interaction patterns, or broader digital literacy barriers. Accessibility,

XSL•FO
RenderX

therefore, should not be understood solely as technical compliance but also as the extent to which an app can be used effectively in real-world contexts by its intended users.

At the same time, some apps demonstrated comparatively strong accessibility and overall quality. For example, within the exploratory WCAG-informed appraisal, MyPills received the most favorable accessibility profile, obtaining "High" ratings across all 4 WCAG principles, whereas Medisafe achieved the highest MAG score (34/39), suggesting particularly strong performance in broader app quality domains. More generally, the studies with the strongest designs reported improvements in medication outcomes, such as medication adherence, self-management, and user satisfaction. However, these findings should be interpreted cautiously, given the limited number of studies, their relatively small samples, and the generally high digital literacy of participants. By contrast, many other apps received low accessibility or quality ratings, and the methodological quality of the supporting studies was mixed overall. Several apps endorsed by organizations still showed substantial accessibility limitations across 1 or more WCAG domains and performed less well on the MAG appraisal. For example, despite being recommended by ONCE and the American Foundation for the Blind, MyFitnessPal relied heavily on visually structured content, complex menu hierarchies, and limited screen reader compatibility, which may reduce usability for individuals who are blind or have low vision. This illustrates a potentially important mismatch between organizational endorsement and real-world accessibility. More broadly, even apps that appeared technically accessible could still be difficult to use in practice because of limited onboarding, insufficient guidance, low awareness, and digital literacy barriers. Taken together, these findings suggest that technical accessibility alone is insufficient; effective dissemination, onboarding, and real-world usability are also essential to achieve meaningful impact.

These findings have several important implications. From a clinical perspective, they suggest that only a small number of apps currently offer reasonably credible and accessible tools for supporting physical functioning, particularly medication self-management. Clinicians may wish to be aware of these options but should also recognize that endorsement or availability does not necessarily imply accessibility, quality, or evidence of benefit. At the same time, the absence of identified apps targeting psychological functioning leaves an important gap in the digital support currently available for this population. From a development, policy, and research perspective, the findings point to the need for more rigorous and transparent standards for app development, evaluation, and recommendation. Apps intended for individuals who are blind or have low vision should be developed through participatory and inclusive co-design processes involving end users, clinicians, and accessibility specialists, and should be evaluated not only for intended usefulness but also for real-world accessibility and usability. This perspective is consistent with recent developments reflected in the WCAG 3.0 Working Draft [62]. Although this document is not a ratified standard, it illustrates an ongoing shift from a predominantly technical, criteria-based approach toward a more flexible framework centered on users' diverse accessibility needs. In addition, future research should prioritize apps that address psychological functioning in ways that are both accessible and clinically meaningful and should include larger and more diverse samples, stronger study designs, and outcomes that extend beyond feasibility or satisfaction to capture meaningful indicators of functioning. Greater attention should also be given to accessible onboarding, guidance, and support features to facilitate sustained real-world use. Finally, future work should examine how emerging assistive and AI-enabled functionalities can be integrated into mobile health apps without increasing complexity or introducing new accessibility barriers.

Limitations

This review has several limitations that should be acknowledged. First, the identified studies were heterogeneous in design, geography, sample size, participant characteristics, and outcome measures, limiting comparability and precluding meta-analysis. In addition, although the present review included studies with qualitative and mixed methods components, it was not designed as a formal qualitative evidence synthesis. Applying frameworks such as those proposed in the Cochrane-Campbell Handbook for Qualitative Evidence Synthesis would entail a substantially different review design but may represent a valuable direction for future research focused on in-depth analysis of user experience and interaction design in this field. Second, restricting the search to English and Spanish publications may have excluded relevant studies in other languages, and despite a comprehensive search strategy, some studies may have been missed. In addition, some apps identified through the literature could not be directly assessed because they were not available for download at the time of review, which may introduce a degree of availability bias. Moreover, identifying apps through organizational recommendations may have introduced selection bias, as not all organizations publish or regularly update such recommendations. This process also introduced geographic and contextual limitations. Several organizationally identified apps were region-specific health care access or administrative tools linked to regional public health systems, which may limit their relevance to international readers and make them functionally distinct from clinical self-management apps. Therefore, the number and nature of identified apps should be interpreted in light of the sources consulted and the organizational recommendation process. Finally, the accessibility appraisal should be interpreted as a complementary and exploratory component intended to contextualize the review findings. It was not designed as a stand-alone usability study, formal accessibility validation, or psychometric assessment. Therefore, its findings should be understood as illustrative user-informed observations of potential accessibility barriers rather than as generalizable estimates of usability or definitive measurements of accessibility across the broader population of users who are blind or have low vision. However, its use is consistent with prior accessibility literature and with W3C guidance supporting the application of WCAG principles to mobile and nonweb software.

Despite the study's limitations, this review shows that the mobile health apps identified through organizational recommendations and the scientific literature remain limited in scope,

XSL•FO
RenderX

heterogeneous in function, uneven in accessibility and quality, and supported by a limited and heterogeneous empirical base. While a small number of apps appear promising, major gaps remain in accessibility, quality, and especially support for psychological functioning. Moving the field forward will require more than simply increasing the number of available apps. Future efforts should focus on developing apps that are accessible from the outset, rigorously evaluated, and developed in collaboration with the people they are designed to support.

Abstract

Background: Skin neglected tropical diseases (NTDs) pose significant diagnostic and management challenges in resource-limited settings due to constrained dermatological expertise, frontline health worker (FHW) training, and limited access to diagnostic resources. Mobile health apps with artificial intelligence (AI)–enabled diagnostic imaging capabilities have the potential to enhance clinical decision-making and professional development at the primary care level. The World Health Organization (WHO) skin NTD mobile app uses convolutional neural networks to analyze images of skin lesions and generate differential diagnoses, intended to be used alongside clinical history and examination, to support FHWs in identifying 12 skin NTDs and 24 common skin conditions. Beyond clinical decision support, the app also aims to upskill FHWs in the recognition and management of these diseases. However, the success of such tools depends on understanding users' needs and the realities of implementation in diverse clinical contexts.

Objective: This study aimed to explore FHWs' perspectives on the real-world use and impact of the AI-embedded WHO Skin NTDs app on diagnostic workflows, dermatological understanding, clinical decision-making, and FHW-patient interactions across diverse health care delivery settings in Kenya.

Methods: This qualitative study involved 36 FHWs from 5 skin NTD-endemic counties in Kenya. Following a training workshop, FHWs integrated the app into routine clinical workflows from June to October 2024. Data were collected through 15 semistructured interviews (each 30 - 45 minutes) and 4 focus group discussions (1 - 1.5 hours) exploring FHW experiences across diverse health care delivery contexts. All sessions were audio-recorded, transcribed verbatim, and thematically analyzed using NVivo (QSR International), using a bottom-up inductive coding approach.

Results: FHWs reported that the app facilitated a shift from habitual referral to more proactive case management at the local-level facility, reinforcing clinical ownership and positioning them as local dermatology reference points. It was perceived to enhance diagnostic confidence, strengthen patient trust, and encourage community engagement. Some FHWs described how the app helped mitigate situations for patient stigma due to decreased reliance on public colleague consultations. However, technical limitations (eg, internet dependency and algorithmic errors) constrained consistent use. While most FHWs used the app in line with its intended role as an assistive tool, a minority reported situations of diagnostic deferral to the AI output, highlighting potential considerations of clinical autonomy.

Conclusions: The WHO Skin NTDs app shows strong potential to strengthen frontline dermatological capacity that aligns with WHO strategies to decentralize NTD care and promote "skin health for all." Our findings underscore the importance of embedding such tools within ethical and pedagogical frameworks that protect clinical autonomy and foster sustainable capacity building. Further research will examine real-world use in situ to guide context-specific governance, ensuring that this AI-embedded tool enhances—rather than displaces—clinical reasoning and epistemic authority.

Introduction

Neglected tropical diseases (NTDs) are predominantly diseases of those in poverty and impact over 1 billion people worldwide [1]. Skin NTDs (which predominantly affect the skin) constitute a significant subset, accounting for nearly half of all NTDs and disproportionately affect marginalized populations in remote rural areas [2]. The World Health Organization (WHO) has categorized skin NTDs together due to their coendemicity, similar initial symptom presentation, common differential diagnosis, and the potential for integrated multidisease control interventions [1]. Despite their widespread prevalence, skin NTDs are often underreported, resulting in an underestimation of their true prevalence and burden on global health [3].

The consequences of skin NTDs extend beyond physical symptoms. Chronic illness, disability, and visible disfigurement often intersect with stigma, social exclusion, and economic hardship [4,5]. These factors delay care-seeking and contribute to ongoing transmission, disease progression, and long-term disability [6]. In many settings, especially in sub-Saharan Africa, access to specialized dermatological care is minimal—with ratios of 1 dermatologist per 500,000 to 1 million people not uncommon. As a result, frontline health workers (FHWs) often serve as the first and only point of contact for patients with skin conditions [7,8].

While FHWs play a critical role in the early identification and management of skin conditions, most have only minimal formal dermatology training [9,10]. For some of the rarer skin NTDs, this knowledge gap is further compounded by limited opportunities for experiential learning and skill retention [11]. While visual examination remains the most accessible diagnostic method, it requires pattern recognition and contextual clinical judgment—capabilities often undersupported in primary care [12]. Furthermore, advanced diagnostic methods such as polymerase chain reaction and microscopy, the gold-standard for diagnosing many skin NTDs, are often unavailable to FHWs at the grassroots level, where most disease detection and management occur [2,11,13].

To address this gap, the WHO has begun to promote a more integrated approach to skin NTD care through its 2021 - 2030 road map, which frames “skin health for all” as foundational to universal health coverage [1]. The strategy emphasizes decentralized care, crosscutting interventions, and capacity-building for FHWs. This agenda was reinforced at the 2025 World Health Assembly where a resolution was adopted recognizing skin diseases as a significant public health concern [14]. Unlike some NTDs managed through mass drug administration, most skin NTDs require individualized diagnosis and longer-term follow-up, increasing the need for clinical decision support at the frontline [2,15]. Enhancing FHW diagnostic dermatological capacity is therefore a strategic priority for reaching skin NTD control and elimination targets [1].

Digital health technologies, particularly mobile health (mHealth) tools, offer promising opportunities to strengthen frontline dermatological care through capacity building [16-18]. More specifically, by embedding artificial intelligence (AI), such as image-based diagnostic algorithms, within these mHealth tools, there is the potential to support FHWs by providing real-time clinical decision support, fostering diagnostic confidence, and facilitating experiential learning in situ [18,19] (in this study, we use this term AI-embedded to refer to mHealth tools that incorporate machine learning models as a defined component of their functionality).

In response to long-standing challenges in the recognition and management of skin conditions at the primary care level, the WHO Skin NTDs app was developed in collaboration with the WHO and No Leprosy Remains [20,21]. The app is designed to assist FHWs in recognizing, documenting, and managing skin NTDs and other common skin conditions, functioning as an assistive clinical decision support tool to enhance clinical diagnostic confidence and capacity [20-22]. The app includes both educational and AI-embedded components, the latter providing image-based differential diagnoses to support clinical reasoning in situ. A more detailed description of the app and its functionality is provided in the Methods section.

However, understanding how such tools are integrated into real-world clinical workflows, and how they may influence clinical reasoning, referral patterns, professional autonomy, and patient experience, is critical. AI-embedded tools in health care can introduce both opportunities and risks, particularly if they shift clinical responsibility or impact human judgment [23]. Evaluating whether such tools are used as intended, and within the boundaries of clinical competence, is therefore central to responsible mHealth innovation and implementation [23]. This study also seeks to examine how the app does or does not support its intended educational use and values, providing evidence to inform its usefulness, and identifying opportunities for iterative design and implementation improvements.

This study explores the use and acceptability of the WHO Skin NTDs app within frontline dermatological care in Kenya, a country with a pluralistic, complex health system and significant gaps in dermatological service provision. Health care delivery in Kenya operates across multiple levels (national referral, county-level, and community-based) [24]. Kenya is endemic for at least 9 skin NTDs including chromoblastomycosis, cutaneous leishmaniasis, post–kala-azar dermal leishmaniasis, leprosy, lymphatic filariasis, mycetoma, scabies, sporotrichosis, and Tungiasis [25,26]. Common skin conditions such as superficial fungal infections are highly prevalent, affecting an estimated 11.57% of the population [27]. Facility-level studies indicate even higher burdens at the point of care; for example,

XSL•FO
RenderX

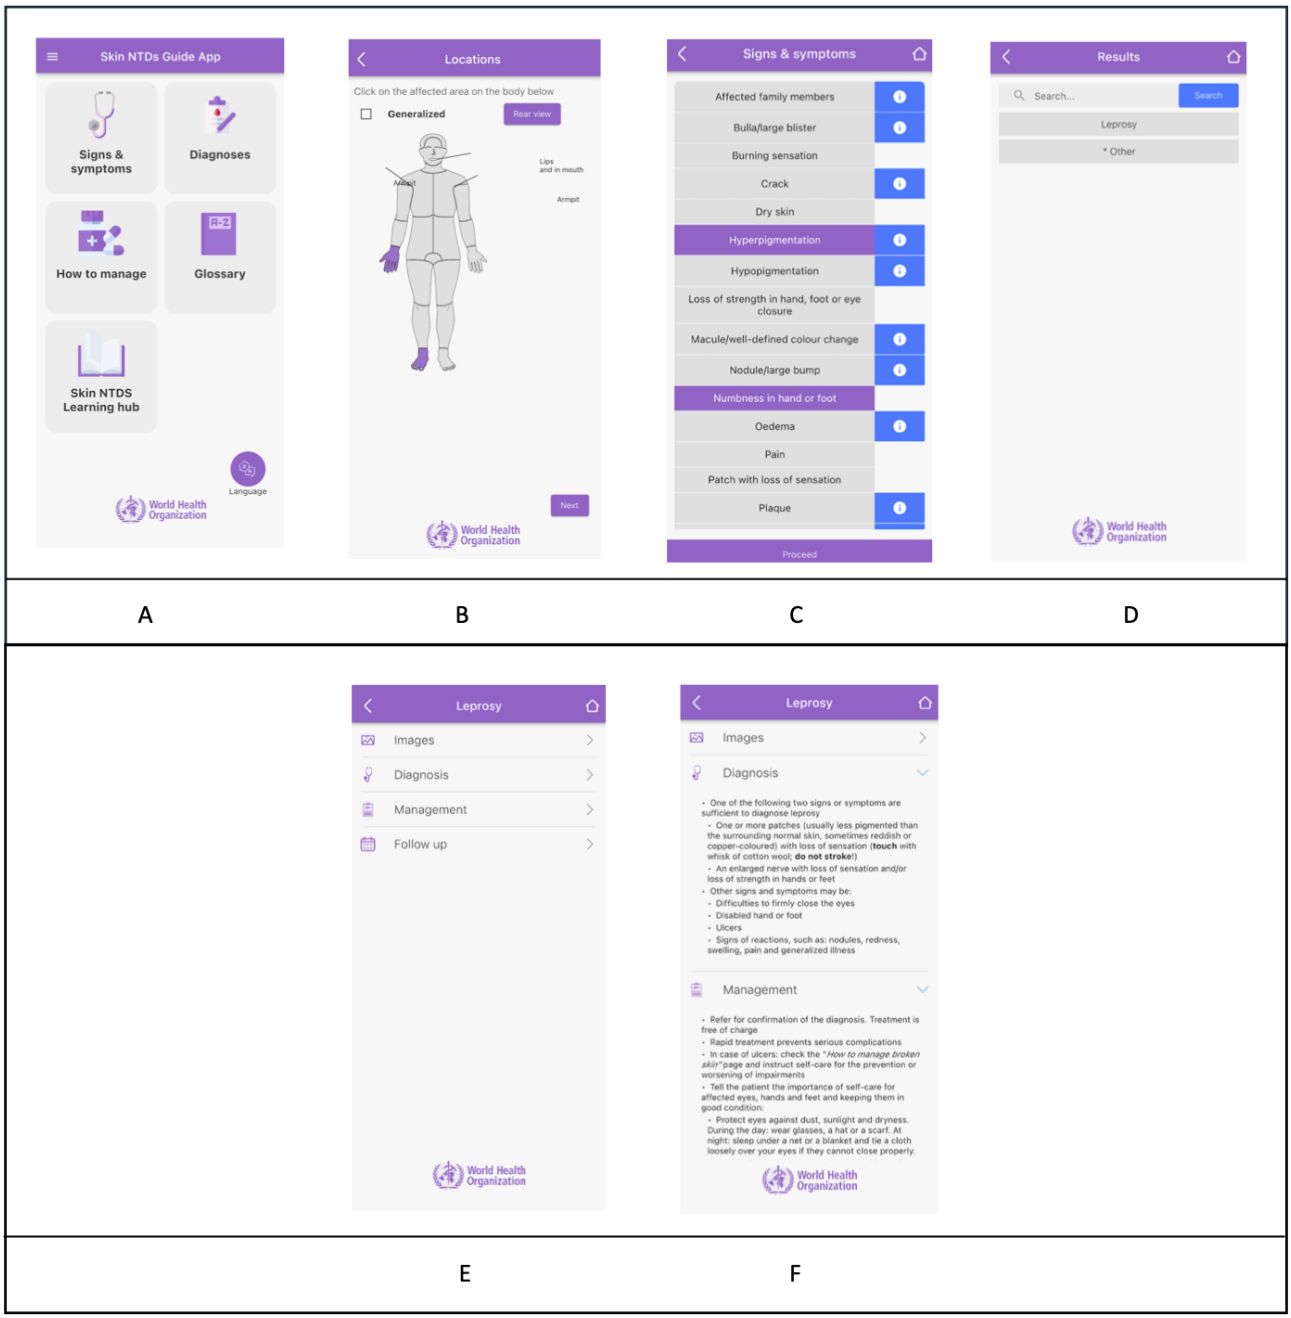
a level 5 hospital in Kiambu County reported eczema in 25.5% of dermatological consultations [28].

This study therefore asks: How do FHWs perceive, interpret, and engage with the AI-embedded component of the WHO Skin NTDs app in real-world clinical settings? Additionally, what do these interactions reveal about the pedagogical, ethical, and systems-level dynamics of deploying AI-embedded clinical decision support tools in primary dermatological care within resource-limited settings?

Methods

The COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist was used to guide reporting, available in Checklist 1 [29].

Study Design



This qualitative study explored the experiences of FHWs integrating the WHO Skin NTDs app into routine clinical workflows across 5 counties in Kenya—Baringo, Nakuru, West Pokot, Kwale, and Kajiado, purposefully selected by the Kenyan Ministry of Health due to their endemicity for skin NTDs. Participants represented FHWs across Kenya's primary health care system, including national referral (level 5), county-level (levels 3 and 4), and community-level (level 2) facilities. Facilities were intentionally sampled across multiple levels of the health system to capture a diversity of clinical and community contexts, resource availability, and workflow structures shaping dermatological care delivery. These levels differ in staffing (eg, nurse-led [level 2] vs clinician-led [levels 3 - 5] services), access to diagnostic and treatment resources, opportunities for peer consultation, and referral pathways. The aim of sampling across multiple facility levels and regions in this way was not to support any systematic formal comparison between levels. Rather, sampling across different facilities and regions provided an opportunity for particular distinguishing factors of these varied settings to be invoked by participants, as appropriate, in their explanatory accounts of usage, perceived usefulness, and impact. Data were collected through focus group discussions (FGDs) and semistructured interviews (SSIs) with participating FHWs. This qualitative component forms part of a broader assessment study on the performance of the app's AI algorithm [30].

WHO Skin NTDs App

The WHO Skin NTDs app comprises two integrated components: (1) an educational component providing structured guidance on diagnosis and management, and (2) an AI-embedded component that generates differential diagnoses from uploaded images of skin lesions. The educational component includes interactive skin lesion localization and condition-specific information, clinical images, and management guidance adapted from the WHO training guide on skin NTDs for FHWs (Figure 1) [5]. This can be accessed during or outside clinical consultations to support learning and decision-making.

Screenshots from the educational component of the World Health Organization (WHO) Skin NTD app. This component coexists with the artificial intelligence–embedded diagnostic functionality (shown in Figure 2) in the current version of the app. (A) Main home screen of the WHO Skin NTDs app; (B) Body map interface used to indicate the anatomical location of skin lesions; (C) Signs and symptoms interface, where users can select multiple features based on the patient's clinical presentation (or for exploratory learning outside the clinical encounter); (D) Results screen displaying potential conditions (eg, leprosy) based on the selected lesion location and symptoms; (E) Condition-specific menu (eg, leprosy) displaying sections for images, diagnosis, management, and follow-up; (F) Example educational content page providing clinical information on diagnosis and management. NTDs: Neglected Tropical Diseases.

XSL•FO
RenderX

Figure 2. Screenshots from the AI-embedded component of the World Health Organization skin NTD app. (A) Interface of the top-level screen for the AI-embedded component, showing 2 entry points for image upload corresponding to the skin NTD and common skin condition algorithms. (B) Image upload interface for the skin NTD algorithm, where users can capture a photograph within the app or upload an existing image from the device gallery. (C) Example output displaying AI-generated differential diagnoses with associated confidence levels for the skin NTD algorithm. (D) Example output displaying AI-generated differential diagnoses for the common skin condition algorithm; "Other conditions" denotes outputs falling outside the predefined set of 24 common skin conditions included in the model. AI: artificial intelligence; NTDs: Neglected Tropical Diseases.

Within the "Signs & symptoms" component, users first indicate the anatomical location of the lesion using a body map interface (Figure 1A). They then select relevant signs and symptoms from a structured list (Figure 1B and C) and based on these inputs, the app generates a list of potential conditions, which users can explore further to access detailed information on diagnosis and management (Figure 1D-F).

The AI-embedded component is based on convolutional neural network models that analyze and classify uploaded skin lesion images. For each uploaded image, the model generates a small set of differential diagnoses with associated confidence levels (low, medium, and high) across 12 skin NTDs and 24 common skin conditions [21,22] (Figure 2). Given that over 80% of skin conditions encountered by FHWs are common skin conditions, their inclusion is essential for clinical usefulness [31].

The WHO Skin NTDs app is designed to be used during routine patient consultations, although no standardized protocol governs its integration within clinical workflows. In practice, use is flexible and embedded within the consultation itself, typically following initial history taking and physical examination. The anticipated workflow involves FHWs capturing an image of the skin lesion with the phone camera, uploading it to both the skin NTD and the common skin condition algorithms, and reviewing AI-generated differential diagnoses. These outputs are then interpreted alongside patient history and clinical examination findings. The app's outputs are not prescriptive; rather, they are intended to support clinical reasoning, enabling FHWs to refine or rule out potential conditions. However, given the app's finite disease library, the true diagnosis may not always be represented.

The algorithm was trained on a dataset comprising 5760 images of skin NTDs alongside 16,577 images of other skin conditions, 2469 images of healthy skin, and 50,000 non–skin images to support classification boundaries [30]. The training set included a diverse range of skin tones, with approximately 70% of images representing dark skin types addressing key concerns around bias in dermatology AI [30,32]. A more detailed account of the app's design, development process, and training approach is provided elsewhere [30].

Participants and Recruitment

Participants were nondermatologist FHWs who routinely manage patients with skin NTDs or common skin conditions at the primary care level. Five counties were purposively selected in collaboration with the Ministry of Health, Kenya. Within each county, health facilities and affiliated FHWs were identified with support from the County Departments of Health. From this sampling frame, 50 FHWs were randomly selected and invited by telephone to participate in an initial training and deployment workshop in April 2024.

Training and Deployment

The training and deployment workshop, held at a centrally located training center in Kenya, introduced participants to the WHO Skin NTDs app. The training combined short didactic sessions with practical exercises. Content included (1) step-by-step instruction on app navigation, image capture, and interpretation of AI-generated differential diagnoses, and (2) guidance on consent practices. Participants engaged in supervised practical sessions where they used the app on peers

XSL•FO
RenderX

to familiarize themselves with consent practices, image capture, and result interpretation.

Following the first training workshop, participants were added to a WhatsApp group with members of the study team to facilitate ongoing technical support and troubleshooting during the deployment period. Participants were invited to integrate the app into their routine clinical practice over a deployment period of approximately 6 months. After the 6-month deployment period, a second evaluation session was convened in November 2024, again at a central location in Kenya. This session focused on understanding participant reflections on their experience using the app and comprised the main qualitative data collection activities. During this session, FGDs and SSIs were conducted to explore participants' experiences using the app, including perceived benefits, challenges, and contextual influences on use. Of the original 50 FHWs invited, 47 attended the first training workshop and participated in the deployment phase. Thirty-six attended the second evaluation workshop and contributed to the qualitative data collection.

Ethical Considerations

This study was approved by the research ethics committee at the Open University of Catalonia, with the Kenyan Medical Research Institute (KEMRI) protocol number KEMRI/SERU/CTMDR/122/4959, Open University of Catalonia reference number CE23-RC21, and the Kenya National Commission for Science, Technology and Innovation license number NACOSTI/P/24/35733. Written informed consent was obtained from all participating FHWs. The FHWs were informed that participation was voluntary and that they could withdraw from the study at any time without any consequences. All FHWs participating in the second workshop provided written consent for audio recording and the use of data for analysis and publication. In addition, FHWs obtained written informed consent from patients before using the WHO Skin NTDs app during clinical consultations during the 6-month study period. Patients were informed that participation was voluntary and that their standard of care would not be affected by refusal to participate. All data were deidentified prior to analysis to ensure participant confidentiality. No personally identifiable information is reported in this study. FHWs were not financially compensated for participating in this study, although travel and subsistence costs (11,000 Kenyan Shillings [1 Kenyan Shilling=US $0.0077 as of June 26, 2026] per FHW, based on government rates) were provided to support workshop attendance. Mobile data bundles (5000 Kenyan Shillings per FHW) were also provided to support app use within clinical workflow.

Data Collection

Data were collected through 15 SSIs (each lasting 30 - 45 minutes) and 4 FGDs (1 - 1.5 hours, 8 - 10 FHW in each). The SSIs enabled a focused exploration of individual FHW perspectives, while the FGDs offered opportunity to encourage debate and consensus building, highlighting areas of agreement and contrast in perspectives on the WHO Skin NTDs app use within diverse clinical workflows. The interviewers (EQ, RN, CC, AF, and DA) used semistructured topic guides to guide FGDs and SSIs, which were reviewed by all authors prior to the workshop (Multimedia Appendices 1 and 2). All FHWs participated in FGDs, and 15 FHWs were purposively selected to participate in SSIs to ensure a balanced mix across counties.

Both SSIs and FGDs were used to enable complementary insights. SSIs allowed for in-depth exploration of personal experiences, with participants asked to recount specific instances of app use in situ. This yielded rich, contextualized accounts of how the app was integrated into individual diagnostic decision-making, including nuanced challenges and variations in use. FGDs, by contrast, enabled group-level reflection, providing a space to examine shared practices, compare perspectives, and identify points of consensus or disagreement regarding the app's usefulness role in workflow and broader systemic challenges. This combination of methods was intended to enhance both the depth and breadth of understanding regarding app integration in routine care.

All interviews and FGDs were conducted in English (an official language in Kenya). Each FGD was cofacilitated by a local research scientist from KEMRI (RN and DA) and a researcher from the Global North (EEVQ and CC). All FGDs and SSIs were recorded on portable Dictaphones and stored on a secured university-licensed cloud service (OneDrive). Field notes were taken by all researchers during and after both FGDs and SSIs and were used to support the thematic analysis.

Data Analysis

Audio recordings were transcribed verbatim by the corresponding author (EEVQ), supporting deep familiarization with the data. Transcripts were analyzed thematically using NVivo (version 14; QSR International) software. Given that this is the first qualitative assessment of the AI component of the WHO Skin NTDs app usability and acceptability, a bottom-up inductive coding approach was selected to support the iterative construction of themes grounded in participant narratives. This exploratory approach aimed to capture nuanced insights that may inform the application of appropriate theoretical frameworks in future studies, as the evidence base on the app's integration expands. EEVQ conducted initial coding of all transcripts. A subset of transcripts was independently double coded by AB and KO. Coding discrepancies were resolved through team discussion, and the codebook was iteratively refined. The full dataset was analyzed using reflexive thematic analysis, with codes inductively organized into 4 higher-order themes within the research team [33].

The derived themes from the analysis made reference to behavioral patterns and interdependencies that lent themselves to communication through systems-thinking visualizations. With this in mind, we constructed 2 causal loop diagrams (CLDs) grounded in FHW narratives to provide a structured way to visualize how system-level dermatological workflow factors interact in practice, both before and after app integration [34]. The intention here is not to generate formal theory but rather to offer descriptive representations of diagnostic and referral pathways and contextual factors shaping their progression as revealed through the FHW accounts. In this respect, the CLDs function as an analytic and communication tool to scaffold the interpretation and presentation of the overall thematic narrative.

Results

Overview

The 36 participants who attended the second workshop in November 2024 comprised FHWs from 5 counties in Kenya: Nakuru (n=11), a fairly urbanized county situated in the Rift Valley; Baringo (n=8), also situated in the Rift Valley, characterized by semiurban and rural areas; Kajiado (n=6), bordering Tanzania in southern Kenya with a seminomadic population; West Pokot (n=8), a remote rural county bordering Uganda, predominantly inhabited by nomadic pastoralist communities; and Kwale (n=3), a largely rural, coastal county in southeastern Kenya [35-39]. Participant characteristics are described in Table 1.

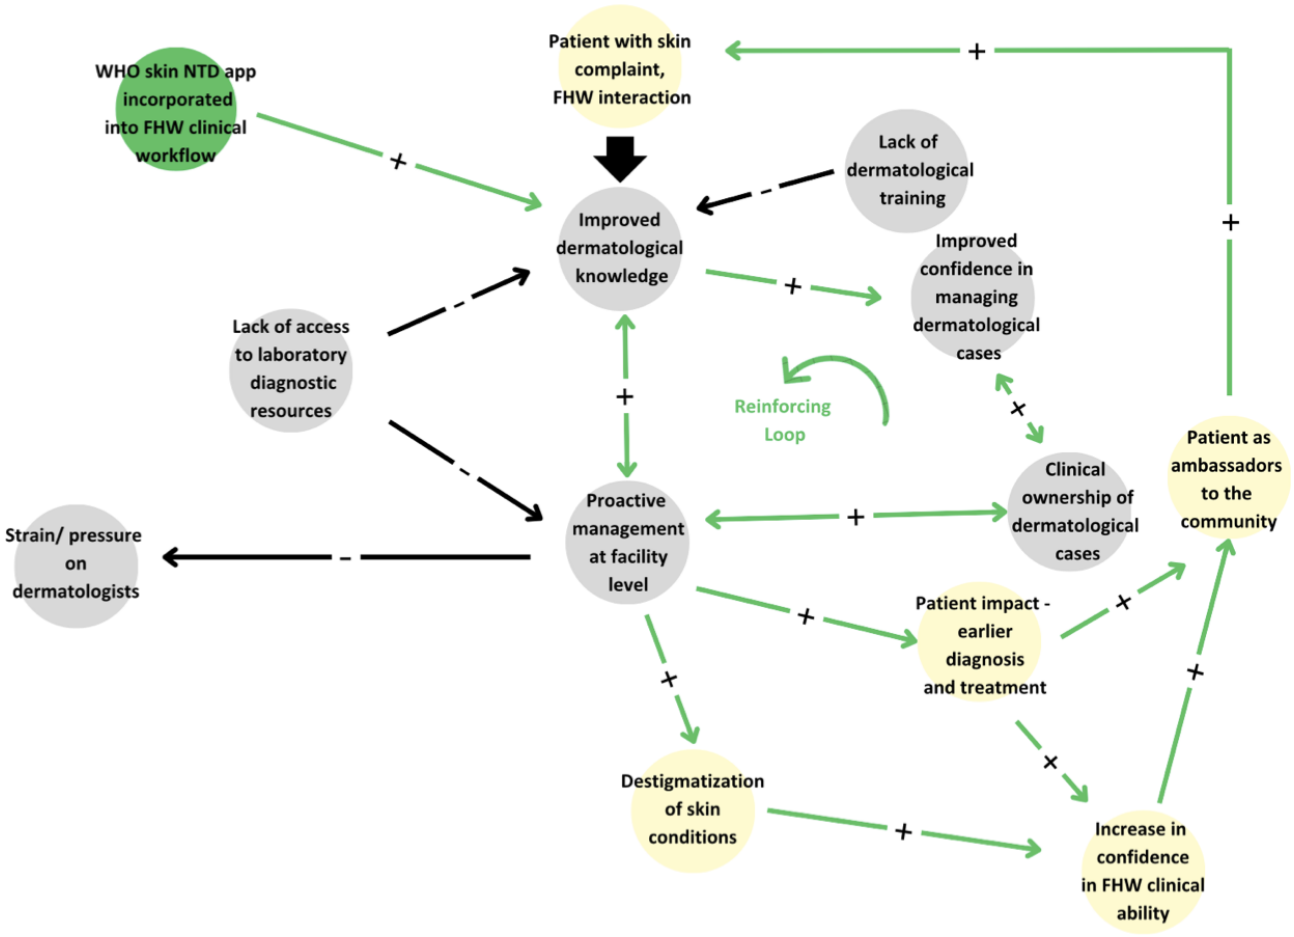
The thematic analysis highlighted shifts in dermatological care delivery, representing the complex dynamics before and after app integration, visualized through 2 CLDs (Figures 3 and 4). The CLDs are grounded in FHW narratives, with illustrative quotes supporting each node (Multimedia Appendix 3). Yellow nodes represent patient-related factors, gray nodes denote FHW-related elements, green arrows indicate changes postapp implementation, and reinforcing loops perpetuate challenges or amplify improvements. Connections depict the relationships between these factors, as articulated by FHWs, indicating whether they have a positive or negative influence. The diagrams synthesize FHW perspectives across multiple facility levels

XSL•FO
RenderX



rather than disaggregated by facility levels. However, we acknowledge that the key elements of aggregated narratives will have a differential impact across the different facility.

Figure 3. Causal loop diagram: preapp context, reported systemic challenges in dermatological care. FHW: frontline health worker; FU: follow-up.

XSL•FO
RenderX

Figure 4. Causal loop diagram: postapp integration and shifts in clinical workflow. FHW: frontline health worker; NTD: Neglected Tropical Diseases; WHO: World Health Organization.

Before app integration, FHWs reported patterns of habitual referral of dermatological cases, where nonspecialist dermatological knowledge often limited immediate diagnostic assessment capability, combined with limited access to diagnostic resources and specialist training that would enable necessary upskilling (Figure 3). This resulted in FHWs expressing a sense of clinical detachment, reinforcing a cycle where FHWs avoided managing dermatological cases at their local facility; instead, depending upon habitual referral to higher-level facilities and specialist services. FHWs expressed that this referral dependency strained dermatology services, which they associated with diagnostic delay and subsequent patient attrition (loss to follow-up). The diagram further highlights a consequent reinforcing feedback loop—the more FHWs referred cases, the less experience they gained in managing them, further diminishing confidence and knowledge in dermatological care.

After app integration, FHWs described a shift toward more immediate dermatological case management at their local-level facility, interrupting the cycle of habitual referral to higher-level facilities and specialist services (Figure 4). The app was perceived as enhancing dermatological knowledge acquisition and development, reinforcing a sense of clinical confidence and greater feeling of ownership of dermatological cases. Local facility case management was perceived to facilitate earlier diagnosis and treatment, which FHWs linked to improved patient trust in their clinical abilities. Additionally, FHWs highlighted the app's role in destigmatization of skin conditions, as greater diagnostic confidence reduced the need for voyeurism of collaborative deliberation over patients. FHWs spoke of patients becoming "ambassadors" within communities, actively promoting care-seeking behavior based on their positive experiences with the app. The diagram further highlights a consequent reinforcing feedback loop—as FHWs gained dermatological knowledge, their confidence in managing cases increased, fostering greater clinical ownership. This, in turn, reduced reliance on specialist referrals as FHWs managed more cases at the facility level, with potential implications for strengthened primary dermatological care.

These system-level causal-loop representations (Figures 3 and 4) offer high-level synthesis of FHW-identified factors influencing the transformation of care and referral pathways. Building on this, we present a deeper dive into the phenomenological accounts of FHW-reported app use and the perceived transformation of practice experienced arising from its adoption.

From Habitual Referral to Local Facility–Based Ownership of Dermatological Cases

The integration of the WHO Skin NTDs app into diagnostic workflows was seen to facilitate a shift from habitual referral to local facility management. FHWs described this transition as improving patient retention and fostering wider community engagement (Figures 3 and 4).

Pre - app: Clinical Detachment and a Clinical Model of Habitual Onward Referral

Before the introduction of the app, FHWs described a sense of clinical detachment from dermatological patients, often perceiving these cases as outside their professional remit (Figure 3). This detachment was largely attributed to "very little knowledge about skin or maybe dermatology" [Participant 23, clinical officer, level 3].

This lack of dermatological expertise seemed to contribute to a "clearing and referring" culture in which dermatological cases were routinely categorized as "clearly not for me" [Participant 3]. Consequently, patients were often referred to higher-level facilities and specialist services without comprehensive clinical assessment (Figure 3). High patient volumes further exacerbated these practices whereby referral, in lieu of clinical knowledge, contributed to a more efficient throughput to help manage overall patient load: "sometimes 120, 130, 150 [patients a day]...you have a lot of patients to attend, it's not only the skin ones" [Participant 13, clinical officer, level 5]. Collectively, FHWs spoke of viewing dermatological conditions as inherently complex and firmly within the domain of specialist dermatologists, reinforcing a reliance on specialist referral as a default rather than a considered clinical choice:

> *The patient with skin NTDs...we didn't want much to know much about it since we didn't know how to make the diagnosis...we didn't want to learn...It was difficult to make diagnosis and in terms of management, it was still difficult for us to manage those conditions...we were not in a position to make that diagnosis...These were conditions that were supposed to be managed by specialist. Specialised people, not by us. Yeah, ours was clearing [patients] and referring...and we wouldn't have followed up.* [Participant 3, clinical officer, level 4]

Notably, some FHWs framed habitual referrals not as an inability to manage but as a need for diagnostic "*confirmation*" [Participant 23], highlighting the potential role of confidence in enabling local facility–based management.

Post - app: The App's Perceived Role in Shifting Toward Clinical Ownership and Local Facility Management

FHWs perceived that the WHO Skin NTDs app disrupted habitual referral patterns by providing clinical decision support, reframing dermatological conditions as more manageable within primary care. Where appropriate, this shift seemed to encourage more immediate and confident management at the local-level facility (Figure 4):

> *We used to refer all patients with skin conditions. But now with the app, we try to manage the patients without sending all of them to the dermatologist.* [Participant 32, clinician, level 5]

Many of the health workers described a developing sense of clinical ownership, actively positioning themselves as local dermatological experts with colleagues now seeking their consultation for dermatological cases:

> *From the time we started using this app, it has, really had a positive impact. Because in our health facility, if anyone comes across a patient with skin lesion, he or she will first send the patient to me. Even if I am off, they will call me..."come and see there is a patient with a skin lesion, come and use the app, we see what is the problem.*" [Participant 21, clinician, level 4]

Impact of Local Facility Management on Patient Retention and Engagement in the Full Illness Trajectory

Before the introduction of the app, FHWs described how their habitual referral patterns would "delay the management or the treatment of this patient." The reasons for this are that the specialist dermatology clinics to which the patients were being referred were infrequent, happening maybe "once in a month or once in a week" [Participant 13, clinical officer, level 5]. As such, patients would be required to wait until the clinics were available and take further time out to travel. In response, many FHWs (notably from level 2 and 3 facilities) described how they informally adopted WhatsApp to enable a limited form of remote dermatological consultations as a workaround. These kinds of practices point to the broader informal integration of mobile phones into everyday health care delivery—an improvised form of telehealth that enables more immediate access to specialist input without requiring patients to travel—in principle, easing the burden of referral. However, FHWs also highlighted the fragility of this workaround, particularly when "sometimes they [the dermatologist] don't even reply" [Participant 19]. Reliance on asynchronous responses from often-unavailable specialists was therefore seen, at times, as a potential source of delay in patient management:

> *OK, I think it [WHO skin NTD app] also saves time since like people who are in a rural facility, when they come across a skin disease and they don't have knowledge about it, they call a dermatologist. And the dermatologist says "take a photo and send it through Whatsapp." So it takes time to get the results. But with the app, it helps diagnosis and you get the patient directly into the system.* [Participant 34, pharmacy technician, level 3]

FHWs widely reported that the app's immediacy of decision support was seen as important in enabling earlier treatment at the local-level facility, reducing the reliance on informal WhatsApp workarounds (Figure 4). Significantly, the subsequent reduction in assessment and treatment delays was felt to be further beneficial in reducing the potential health complications associated with treatment delay:

> *It [WHO skin NTD app] is a key app for any primary healthcare worker, because one, it's going to help in giving the treatment to the patients...it's going to stop delay in giving the patient treatment. And that will reduce the complication associated with each particular condition depending on each condition you are dealing with. "Cause as we delay, there are problems of that condition.*" [Participant 18, clinician, level 5]

Managing dermatological patients at the local-level facility was widely reported as "cost-effective for our clients" [Participant

XSL•FO
RenderX

2], reducing both direct costs (eg, transport and consultation fees) and indirect costs (eg, loss of earnings due to travel and appointment wait times). FHWs linked these cost savings to improved patient retention, with fewer patients "defaulting" from care [Participant 2]:

> *The impact to my patient...it has helped so much because it will reduce the cost because generally rather than the patient having to go and look for a dermatologist in Nairobi or in another place, you are able to make that diagnosis [at the facility level] and help that patient.* [Participant 13, clinical officer, level 5]

Some FHWs also reported a sense that patient confidence in local facility–based care improved with app use. They described that for some patients, seeing the app used in their consultation through digital imaging of their skin lesion appeared to foster "a lot of hopes—that maybe here the treatment will come..." [Participant 9, nurse, level 5]. However, there were also reports that some patients remained skeptical of the app, particularly those with prior experiences of misdiagnosis. This skepticism was often expressed as hesitancy around image capture. As one FHW described: "One [patient with a skin condition] was saying 'I have been facing several dermatologists without any improvement, so why would I assist you with consent to take a photo from part of my body?'" [Participant 25, clinical officer, level 5]. Similarly, others described that prolonged illness trajectory appeared to shape patient perceptions of the app's value "someone has maybe a lesion for a very long time, then...'here you are, you want to take a photo of that lesion. So, what difference will it make?'" [Participant 22, clinical officer, level 3].

Impact of More Immediate Local Facility Management on Community Engagement

Multiple FHWs described an unexpected outcome of earlier facility-level management. Having experienced the app's role in clinical decision support, FHWs reported that patients then encouraged others to seek similar care, emerging as informal community "ambassadors" [Participant 25], seemingly facilitating peer-driven health-seeking behavior (Figure 4):

> *And also to the community, once you use the app in diagnosing one patient, he or she will go on, referring another one, "go to the facility, the nurse will take a photo.*" [Participant 29, nurse, level 2]

FHW associated this community advocacy with "hope," driven by the belief "that there is something that will come out of that [the app]" [Participant 24, nurse, level 2].

From Limited Dermatological Knowledge to Perceptions of Increased Knowledge and Confidence in Case Management

Findings suggest that the shift from habitual referral to local facility case management was driven by FHWs' perception of improved dermatological knowledge, in turn enhancing clinical confidence (Figures 3 and 4). The majority of FHWs suggested that the app did not replace clinical judgment but seemed to reinforce it—functioning as an assistive tool that encouraged active engagement with differential dermatological diagnoses.

Knowledge Acquisition and Development Through Diagnostic Comparison and Self-Directed Education

The app's provision of differential diagnoses appeared to encourage curiosity, with many FHWs describing how this broadened their clinical awareness of skin conditions (Figure 4). Encountering unfamiliar or unexpected diagnostic suggestions seemed to prompt more active clinical reasoning, including questioning, comparison, and reflection on local disease patterns. As one FHW described:

> *...it has opened my mind more, giving me more learning on a lot of exposure to many conditions...you take a photo, it says Yaws, and Yaws is not common in that region. So you get suspicious...why? So you have to ask several questions....* [Participant 13, clinical officer, level 5]

FHWs also described engaging in self-directed learning in response to these prompts, seeking additional information through books and online resources when presented with unfamiliar conditions. One participant noted that the app "challenged [their] knowledge" and motivated them "to go and read...to understand more about the disease" [Participant 33, clinician, level 2].

Beyond knowledge acquisition, FHWs noted a deliberate process of comparing the app's differential diagnosis— referred to by some as "impressions" [Participant 3]—with their own clinical assessments. This comparative process involved integrating patient history, physical examination, and app output to support diagnostic reasoning: "...once I ask the app what is their opinion, it's it will help me see if my clinical judgement is next to what the app is actually saying" [Participant 18, clinician, level 5]. FHWs emphasized how this process enabled them to refine, rather than replace, their clinical judgment. The app was described as providing "room" to rule out or reconsider working diagnoses based on likelihood and clinical context [Participant 21].

While the app was widely perceived as supportive, most FHWs recognized that its outputs were not infallible. As one participant noted, it should be used as "support...and then you add to the knowledge you have" [Participant 19]. However, engagement with the app varied, with a minority of FHWs expressing high levels of reliance on its outputs, at times treating them as definitive and "100% this is the skin condition" [Participant 1, public health officer, level 5]. In cases of diagnostic discrepancy, FHWs reported prioritizing peer consultation over defaulting to the app's output, emphasizing the continued importance of clinical judgment and collaborative decision-making. As one FHW reflected: "You have to still have your own clinical judgment...If you don't agree [with the app output]...you must consult" [Participant 6].

Confidence Gains as an Outcome of Incremental Knowledge Acquisition and Development

FHWs reported their "confidence building up" in dermatological case management as they perceived development in their dermatological knowledge through continued app use [Participant 19, clinician, level 2].

XSL•FO
RenderX

> *So it [the app] has impacted me positively because now I'm very confident to tackle any skin condition rather than before. Before seeing that patient, you can see the patient from far and then you are thinking me how am I going to manage this patient now? Where can I start, from what you see? But when this app came, you have that confidence to see that patient and come up with a diagnosis.* [Participant 11, clinical officer, level 4]

Importantly, this confidence was not derived from blind reliance on the app's output but from the alignment between the app's suggestions and FHWs' clinical judgment. When the app's diagnostic suggestions corroborated their own clinical assessments, the majority of FHWs reported an increased "morale" and motivation to engage more deeply with patient management:

> *The positive part is that when you come into contact with a client, and then you use the app, and the app says the exact diagnosis you have been thinking of clinically and then you feel comfortable in managing the patient. And then that morale of doing more for the patient comes in.* [Participant 12, clinician, level 4]

This confidence was further reinforced by the app's availability as a "backup" [Participant 23] tool, particularly in settings where dermatological expertise and resources were scarce:

> *If I have something that I'm not very sure, I'm not worried or I'm not anxious because I know I have the app, which is a tool that can assist me... I'm confident because it's like knowing there's somebody here who can, you can always consult and refer to...I'm sure that there's somebody who can help me. And that's somebody is the app.* [Participant 23, clinical officer, level 3 (Figure 3).]

Reduced Dependency on Public Deliberation Increases Patient Trust and Alleviates Stigmatization of Patient as a Clinical Spectacle

Before app integration, FHWs reported that one consequence of limited dermatological knowledge was the felt need to call multiple colleagues, "maybe even 2-3 people to come to the same room and discuss the patient" [Participant 13]. While perhaps intended as a means of clinical support, many FHWs reflected on how this public deliberation created awkward and uncomfortable situations for patients, reinforcing stigma around dermatological conditions (Figure 3):

> *Before, every time they [the patient] comes, we call each other "come confirm if this is leishmaniasis, come confirm if this is leish"...By the time you are calling more people to come and see, you see, the patient feels stigmatised.* [Participant 2, nurse manager, coordinator]

Beyond stigma, FHWs observed that patients often perceived these public deliberations—conducted in front of the patient (and distinct from standard peer consultation outside the consultation space)—as a sign of clinical uncertainty, reducing trust in their ability to provide appropriate care. Participant 2 elaborated:

> *...if a patient comes in and you are not sure of the diagnosis, the patient may feel that this clinician is not confident. Why has the clinician have to call others to come and verify the diagnosis, it means that the clinician is not confident enough...even the clinician doesn't know what I'm suffering from. They will not even feel confident with the treatment that you write for them.*

However, with the app as "a partner that can help you make a diagnosis," FHWs described an increased confidence to make clinical decisions more independently, "instead of calling a colleague, several clinicians to come" [Participant 15]. FHWs reported that this shift contributed to a reduction in stigma, as patients were no longer subjected to group deliberations during diagnosis:

> *Before we get hold of this app, when you see a condition where you suspect this is an NTD, you have to call your colleague, maybe even 2 - 3 people to come on to come to the same room and discuss the patient. So, for now at least, there is that reduction in the stigma because you are only with a patient. So, there is a lot of confidentiality.* [Participant 13, clinical officer, level 5]

Opportunities to Extend Knowledge Development Beyond Clinical Decision Support to Full Illness Trajectory

While the app was reported to support dermatological learning and diagnostic reasoning, many FHWs reported that it "is limiting in terms of management… it does not give us information on treatment." This limitation added complexity to clinical workflows and often required FHWs to "use the app alongside Google...to find how to treat" [Participant 8, clinician, level 5]. Although the app does contain management guidance in a separate section, FHWs envisioned embedding treatment and management guidance directly after diagnostic suggestion to help reinforce incremental learning across the full illness trajectory. Participant 8 went on to explain: "...it would be better if, for the purpose of frontline workers who really don't have a lot of knowledge in dermatology, every information comes to the app so that once you have said that you have uploaded the photo, you get a diagnosis, get treatment."

The WHO Skin NTDs App Facilitating Patient Involvement in the Diagnostic Process

Findings show that the integration of the WHO Skin NTDs app into clinical workflows appeared to shift diagnosis from a clinician-driven process to a more participatory model, actively involving patients in their care. Initial narratives from FHWs indicate that the app seemed to function as both a clinical decision support tool and a patient engagement mechanism.

Strengthening Patient Involvement Through Diagnostic Transparency and Participation

FHWs described how, for some patients, seeing the app's interface and diagnostic suggestion appeared to reinforce engagement in their own care:

XSL•FO
RenderX

> *This app, when I used it on my patients, they were a bit happy because when I showed them the diagnosis [on the app], we could share together. So, most of them were actually happy because of the technology.* [Participant 5, clinician, level 5]

The app also appeared to promote more interactive consultations, with some patients becoming increasingly engaged in discussions about their skin conditions and expressing curiosity about the diagnostic process:

> *This time around when you are using the app you explain to the patient more and also the patient was curious to know more about, about the app and sometimes also they were curious about the skin diseases. Maybe they could ask you, "have you ever seen maybe a skin disease like this with anyone else, or is it? Or is it me alone? So, there was a lot of discussion between the patient and me now. They'll tell you..."this time around the way you have explained to me, I think I'll get well."* [Participant 22, clinical officer, level 3]

Beyond sharing diagnostic suggestions, FHWs felt facilitated by the app in engaging patients in real-time diagnostics, making consultations more collaborative. In turn, FHWs attributed this increased participation with strengthened patient confidence:

> *Participant 3 [clinical officer, level 4]: ...the best thing is to involve your patient in the [diagnostic] process.*
>
> *Interviewer: And the app allows you to do that?*
>
> *Participant 3: Of course, whenever you're using it, it is our phone. You know, the way we sit together, the way we sit with our patients in our facility. My patient will come. OK we sit at an angle we normally use a system [computer system], this patient wherever he's sitting he will have to see the system...It's almost next to each other...So, the patient can see everything you're doing...so at least the patient will follow the process, and by the end of the day, he'll see the diagnosis that you get from the app. So, it is still build confidence in this patient.*

Technical Limitations and Their Impact on Patient Involvement in the Diagnostic Process

FHWs described varied experiences with internet connectivity, which shaped their ability to use the app in real time and, in turn, influenced the participatory nature of consultations (the AI-embedded component of the app currently functions online only). Some reported no issues "in terms of connectivity" [Participant 3], while others anticipated connectivity issues but developed workarounds such as identifying areas with stronger signal:

> *My first impression was since the app is using data bundles, and connectivity in my area is a bit poor. So, I thought it would give me a really hard time uploading the photos, which wasn't the case so much because I designated an area that was a bit faster.* [Participant 24, nurse, level 2]

However, in more rural settings, FHWs described network dependence as a major limitation, preventing the app from being used consistently: "I think the challenging part of this app is the problems when there is no network...so you cannot use the app... in rural facility...you cannot assist the patient using the same app" [Participant 12, clinician, level 4].

Beyond connectivity, specific technical failures disrupted patient involvement more directly. One recurrent issue was the unsettling error message "not human skin" [Participant 36], which appeared during attempts to capture images in live consultations. Despite multiple adjustments, this issue often persisted: "The first time I got the response of not a human skin. I kept on trying several times, like increasing the light, maybe the light was low, changing postures...I tried several times, but still it failed" [Participant 32, clinician, level 5]. Such breakdowns seemed to introduce moments of uncertainty during consultations, undermining both interactional flow and patient confidence. As one FHW reflected:

> *The problem of course is when the patient looks at you it also gives stigma to those patients. Including myself...you are wondering "what I am doing, am I doing the right thing." It's the patient and me, and the patient trusts me, and I look like this thing is not working then the patient also thinks 'he does not know what he is doing, using this app.* [Participant 1, public health officer, level 5]

In some accounts, some FHWs attributed this error message to the technology's failure to recognize darker skin tones:

> *Another disadvantage as part of it is when you take a photo, especially in our place, you see the African skin, the app will tell you that's not a human skin.* [Participant 12, clinician, level 4]

Interconnectedness: Expanding the Role of the WHO Skin NTDs App

FHWs envisioned the WHO Skin NTDs app evolving beyond its current role as an assistive tool for capacity building within the individual clinical encounter. Their recommendations highlighted its potential to function as part of an interconnected health system, linking clinical dermatological care with broader health system infrastructure.

Connecting Clinical Services and Integration Into Local Digital Infrastructure

The majority of FHWs emphasized the importance of embedding the app within existing digital health systems, particularly Kenya's electronic medical record (EMR), to streamline clinical workflows and facilitate referrals. Integration was viewed as important for both sustainability and routine care.

> *Using the computer system [EMR], it could improve the referral system for so many clients from skin NTDs to the facilities. So, there maybe should be a connection between the app in their phone and the gadget in the facility.* [Participant 17, public health officer, level 3]
>
> *The Kenya Government is encouraging the digitalisation of the health system...So, any system*

XSL•FO
RenderX

> *which is coming, any digital app which is coming, it has to be interoperable with those systems of government [Kenyan EMR]. Those ones, it's just helping in terms of data management, not in terms of diagnosis.* [Participant 10, clinician, level 4]

These insights highlight a potential opportunity for additional interoperability, with the app positioned not as a stand-alone tool but as part of an integrated digital ecosystem supporting sustainable service delivery.

Connecting Clinical Services to Broader Public Health

FHWs commented how greater interoperability could potentially facilitate closer alignment with national health systems in ways that could further benefit broader public health. Beyond point-of-care decision support, the app was imagined as a tool for real-time disease surveillance, resource mobilization, and data-informed planning.

> *It [the app] will also help in resource mobilisation. Because at the community level, at the lower level, level 1, level 2, level 3, you will be able to know those diagnosis using the app and the clinician judgment. So through the county, our leadership will be able to know 'this area has this number of cutaneous [leishmaniasis], and then they will pull the resources to that area so that they can deal with that condition.* [Participant 15, community health nurse, level 2]

While not framed as formal design principles, these insights point to the importance of designing AI-embedded mHealth tools that are responsive to existing digital infrastructures and aligned with routine clinical workflows, rather than functioning as stand-alone applications. Further ethnographic work will enable more fine-grained articulation of how such integration is enacted in practice.

Discussion

Principal Findings

This study presents a comprehensive understanding of FHWs' experience and perception of the WHO Skin NTDs app in Kenya. The majority of FHWs described the app as facilitating the following: (1) validating their clinical judgment, which reduced dependency on referral pathways and improved patient retention and community engagement; (2) incremental knowledge acquisition and growing confidence in managing dermatological conditions independently; and (3) enhanced patient engagement and perceived trust in the diagnostic process.

These findings contribute to a growing body of evidence on how mHealth tools are being integrated into resource-limited frontline health systems and the ethical and pedagogical challenges this raises, particularly given the app's intended function as an educational and capacity-building tool [21,30,40]. By contrasting FHWs perceptions of pre- and postapp clinical workflows (Figures 3 and 4) and integrating FHW narratives (Multimedia Appendix 3) with thematic analysis, we identify potential system-level challenges associated with dermatological care and specific mechanisms of change facilitated by the app. These insights inform both app refinement and broader implementation strategies to maximize pedagogical value and ensure ethical integration of mHealth tools in frontline health care systems. Taken together, they suggest that the app is having a positive impact on dermatological care within the studied context and is, in many cases, being used in alignment with its educational remit. However, there remains a need to examine edge use cases and potential risks—particularly where usage may extend beyond the app's original design parameters [23].

Clinical Improvisation and AI-Supported Reasoning

This study highlights the central role of clinical improvisation—real-time adaptation of clinical workflows and care strategies—as a core component of dermatological care in resource-limited settings [41,42]. In sub-Saharan Africa, FHWs routinely navigate complex social, political, infrastructural, and economic constraints, necessitating clinical improvisation [41]. FHWs identified multiple systemic barriers impacting dermatological care, including limited diagnostic resources, inadequate training, scarce dermatology expertise, and high patient volumes (Figure 3). In response, they described improvisational practices such as habitual referral, informal WhatsApp consultations, and public deliberation of clinical cases (Figure 3). Crucially, these practices are not merely indicative of knowledge gaps or health system limitations; rather, they reflect locally adapted strategies developed under constraints, described elsewhere as the "craft" of care under constraint [41].

However, while such strategies may enable care delivery where formal systems fall short, our findings suggest that some may also inadvertently limit opportunities for building and maintaining dermatological knowledge and case management skills. In this study, FHWs linked habitual referral and reliance on external consultation to diagnostic delays, patient attrition, and stigma–patterns observed across similar African contexts [43,44]. These findings suggest that some adaptive strategies may unintentionally reinforce ongoing dependency on specialist services by reducing opportunities for local dermatological knowledge development and case management experience.

Our findings suggest that integrating the WHO Skin NTDs app into clinical workflows may help reshape improvisational practices by facilitating more reflective diagnostic reasoning and greater confidence in local facility case management. While some of these benefits may also arise through other forms of clinical decision support, the AI-enabled nature of the app allows FHWs to compare image-based differential diagnoses with their own clinical assessments in real time.

In the broader literature, AI-embedded tools are ideally situated within a model of human-AI symbiosis: a collaborative relationship where the clinician's reasoning complements the algorithm's suggestions [45,46]. Most FHWs in our study described using the app in these terms—referring to it as a "partner" [Participant 15], akin to a second reader that supports and moderates, rather than supplants, their clinical judgment. FHWs reflected that this perceived partnership enabled more confident and independent patient management at the local-level facility, reducing reliance on improvisational workarounds such as habitual referral. This could be interpreted through the lens

XSL•FO
RenderX

of self-efficacy theory, which posits that an individual's engagement in a behavior is related to their belief in their ability to perform such tasks [47]. In this context, the app appears to function as a mechanism for enhancing FHWs' perceived self-efficacy in dermatological care, supporting their ability to act on clinical decisions locally. This reflects wider literature on how AI-embedded clinical decision support systems can be, and should be, designed to augment rather than replace human reasoning [46,48].

However, our findings also suggest that when the app's output did not align with the FHW's clinical judgment, FHWs often reverted to referral to specialist dermatologists. While this can be understood as an appropriate response to clinical uncertainty, it also highlights an important opportunity for future design refinement. AI-embedded decision support tools may benefit from incorporating structured support mechanisms to guide arbitration in such cases, ensuring that the burden of resolving diagnostic discrepancies does not fall solely on the FHW. Such mechanisms could further enhance the app's pedagogical value by facilitating reflection and learning through structured resolution pathways, rather than relying on referral as a default form of risk mitigation.

Ethical Tensions: Maintaining Clinical Autonomy in AI-Supported Care

Our study raises a potential ethical concern with respect to how some FHWs may inadvertently use the app beyond its intended remit as an educational clinical decision support tool, potentially engaging in care beyond their clinical competence [23]. One FHW, for example, explicitly described deferring entirely to the app's diagnostic suggestions. This pattern may reflect elements of automation bias, whereby users place undue trust in algorithmic outputs over their own clinical judgment [49]. Given the limited dermatological knowledge reported by FHWs, such potential overreliance may raise medicolegal and ethical concerns [23].

Some scholars caution that as AI systems are perceived to outperform human judgment, they may begin to displace human epistemic authority [50]. This risk is echoed in broader literature, which highlights that AI tools may contribute to clinician deskilling, diminished critical reasoning, and reduced capacity to navigate complex or atypical cases through overreliance [48-53]. While often discussed as a future-facing concern, our findings suggest that elements of this dynamic may already be emerging in contexts where dermatological expertise is limited [50]. In such cases, for some FHWs, the app's output may be seen not as suggestive but as directive—an inversion of its intended role.

Meaningful human-AI collaboration depends on users having sufficient knowledge to question and validate algorithmic suggestions—a process that relies on training, confidence, and the time and institutional space to exercise clinical judgment [46]. Many FHWs in our study described using the app in this way, comparing AI-generated differentials with their own clinical assessments and reporting perceived knowledge gains through continued app use. Such experiences may, over time, strengthen their capacity to engage critically with AI outputs. Conversely, where foundational dermatological knowledge is limited, the same system may increase the risk of inappropriate reliance on algorithmic suggestions.

This presents a paradox in the positioning of the WHO Skin NTD app. The tool is explicitly designed to support capacity building among FHWs in response to limited dermatological expertise [21,22,30]. Yet, for the app to be used responsibly, FHWs must possess sufficient baseline knowledge to critically interrogate and contextualize its outputs. As our results suggest, this prerequisite cannot be assumed and is likely to vary significantly across different health system contexts, facility levels, and individual FHWs. To help mitigate this risk, explainability of AI outputs is critical: presenting outputs in transparent, interpretable ways can better support FHWs in understanding and validating diagnostic suggestions [54]. Other human-centered design principles, such as offering contextual guidance and supporting stepwise reasoning, could further assist FHWs in maintaining epistemic authority while engaging with the app. Features already present in the app, such as graded confidence levels associated with differentials, may help surface diagnostic uncertainty in ways that encourage critical engagement [54-56].

In addition to this epistemic tension, it is critical to recognize that the dynamics of AI use in clinical practice are not shaped by individual knowledge alone. Broader contextual factors, including patient load, time constraints, and infrastructural limitations, also influence how AI outputs are interpreted and acted upon [45]. This reinforces the importance of designing and adapting AI tools and implementation strategies in ways that explicitly protect and promote clinical autonomy, both in individual decision-making and across broader health care delivery [45,57,58].

Three areas of further work are needed. First, direct observation of app use in situ will be critical to understanding how it is conceptualized in practice, how broader contextual factors shape its use and whether it is functioning as intended (as a clinical decision support tool used for educational purposes within the clinical encounter), or whether some usage patterns risk reclassification. This will also be critical for elucidating how patients perceive the app's role in the collaborative context of FHW-patient interaction. Second, targeted design adaptations, such as embedded disclaimers or periodic training modules, should be explored to reinforce the app's role as a nondirective support tool and bolster FHWs' dermatological knowledge to safeguard clinical autonomy. Third, development of a context-specific professional ethical guidance framework for health care AI use (PEG-AI) may be necessary to ensure the safe, responsible, and ethically robust integration of the app into frontline care [23]. PEG-AI offers a context-sensitive governance approach for AI-embedded tools, essential for ensuring ethical implementation in resource-limited settings and safeguarding clinical autonomy, regardless of medical device classification [23].

Maintaining the use of the app within the boundaries of clinical competencies is therefore not solely a function of the tool itself but depends on the interaction between design features (eg, explainability, confidence indicators, and embedded guidance)

XSL•FO
RenderX

and broader system-level supports, including training, workflow integration, and context-specific ethical governance.

Situated Learning

In our study, only 1 FHW had ever heard of the WHO manual "Recognising Neglected Tropical Diseases Through Changes on the Skin: A Training Guide for Frontline Health Workers" [5]—a training guide specifically developed to build dermatological capacity among FHWs in resource-limited settings. Interestingly, the entire contents of the app are derived from this manual. However, our findings suggest that the format in which the information is both accessed and delivered shapes engagement and learning. While the manual offers comprehensive guidance, its didactic, decontextualized format perhaps separates learning from real-world clinical application. By contrast, the app delivers this same content in ways that are tailored to individual clinical cases, offering real-time feedback and follow-up information that are directly tied to patient encounters. Embedded in the relational space of the consultation, the app appears to support experiential, situated learning [59]. This aligns with well-established principles from the situated learning literature which emphasizes that learning is most effective when embedded within authentic contexts of practice [60-62].

In optimal conditions, the affordance of a continuously connected mobile device likely enhances this mode of learning. However, in our study, limited internet connectivity emerged as a barrier to consistent app use. Ensuring that the app's AI algorithm functions offline will be essential for equitable and sustained integration—an improvement the WHO Department for NTDs is currently exploring.

System-Level Impact and Referral Pathway

Existing literature suggests that over 80% of dermatological cases encountered by FHWs at the primary care level are common skin conditions, which are generally simpler to diagnose and manage [31]. In our study, FHWs reported that the app supported their ability to identify and manage these common skin conditions, often confirming their clinical judgment and enabling local facility management. However, when confronted with complex cases—particularly suspected skin NTDs—our findings show that FHWs remained more likely to defer to specialist referral, especially when the app's diagnostic output could not be corroborated by their own limited dermatological knowledge. This pattern aligns with a key dimension of the PEG-AI framework which emphasizes that AI-embedded tools should be used within the boundaries of clinical competencies [23].

In this context, the WHO Skin NTDs app appears to strengthen local dermatological care by enabling FHWs to manage common skin conditions more confidently, potentially reducing unnecessary referrals. This may help alleviate pressure on overburdened dermatology services, allowing specialists to focus on more complex or rare presentations, particularly skin NTDs.

However, this shift in clinical workflow introduces algorithmic implications. As FHWs increasingly retain patients at the facility level, the accuracy of the algorithm becomes more consequential. In such cases, it may be preferable for the algorithm to prioritize sensitivity over specificity (ie, to favor false positives over false negatives) to minimize the risk of missed cases, particularly as reliance on referral as a default pathway has declined (Figures 3 and 4).

This shift also raises important system-level considerations. While strengthening that facility-level management may improve access to care and reduce pressure on referral systems, it may also introduce new risks. If only suspected skin NTDs cases are escalated—while structural barriers to referral (such as distance, cost, and dermatologist shortages) remain—patients with complex dermatological conditions may still face delayed diagnosis and discontinuity of care, particularly in rural and underserved areas.

Assessing the full impact of AI-embedded tools such as the WHO Skin NTDs app—both intended and unintended—requires moving beyond the individual clinical encounter to examine how such tools reshape referral pathways, clinical workflows, and health system capacity. A systems-level process evaluation will be essential to understand these dynamics and their implications for patient outcomes, including health economic considerations [63,64]. This aligns with broader calls to evaluate mHealth interventions not only at the point of care but across the full health system to surface both enabling factors and unintended consequences [65].

Illness Trajectories

A key challenge frequently reported by FHWs was the lack of immediate management and follow-up support following the app's diagnostic suggestions. While the app provides AI-generated diagnostic suggestions instantaneously, the accompanying disease management guidance—although present—is in a separate section on the app and not seamlessly integrated into the clinical decision support workflow. This design choice may inadvertently reinforce a fragmented view of care, privileging diagnosis as an endpoint rather than as part of a broader continuum that includes, for example, management, follow-up, and psychosocial support [41]. This is particularly relevant, given the chronic course and complex illness trajectories associated with many common skin conditions and skin NTDs [66].

Enhancing the app's capacity to comprehensively support FHWs across the full illness trajectory—by embedding management guidance directly after diagnostic suggestion—could significantly broaden its value. The section of the app describing how to diagnose and treat each skin disease incorporates links to targeted training modules or embedded decision pathways (such as those aligned with WHO Academy resources) to better equip FHWs to deliver holistic, sustained care that responds to the complex and chronic illness trajectories of dermatological conditions [67].

Limitations

This study has several limitations. First, findings reflect the perspectives of FHWs only; patient perspectives on the app's influence on care, agency, and experience were not explored. This is a key aim that will be addressed in forthcoming ethnographic fieldwork. Second, FHW responses may have

XSL•FO
RenderX

been influenced by social desirability bias, given some of the research team's involvement with the app's development. However, independent facilitation was used to mitigate this risk [68,69]. Third, reported shifts in care may reflect short-term novelty effects rather than sustained practice change [70].

While this study aimed to generate a systems-level understanding of the app's implementation, future research should complement this with detailed patient pathway mapping and comparative studies across diverse contexts to assess transferability [62]. Of the 50 FHWs initially enrolled, 47 participated in the training and deployment phase, and 36 FHWs attended the follow-up workshop where qualitative data collection occurred (72% follow-up). This is notable, given the wide geographical spread of participants and the logistical barriers involved in attending a centralized workshop. All 5 counties were represented among those who attended. However, it is possible that nonattendees had lower engagement with the app during the deployment phase, although no definitive reasons were provided for their absence. This potential attrition bias should be considered when interpreting findings.

Conclusions

This study offers preliminary insights into the ways FHWs perceive the AI component of the WHO Skin NTDs app is reshaping frontline dermatological care in a complex, resource-limited health system. FHWs reported that the app supported more confident local-level facility management, disrupted habitual referral patterns, and fostered incremental knowledge acquisition. Importantly, our findings highlight the ethical and pedagogical complexities of integrating AI-embedded tools into frontline care. While FHWs reported that the app often strengthened clinical reasoning and learning, risks of overreliance and unintended shifts in clinical autonomy remain, particularly where baseline dermatological knowledge is limited. Future research should explore these dynamics through in situ observation and pathway-level evaluations. With continued attention to both pedagogical value and ethical governance, the WHO Skin NTD app has strong potential to advance the WHO's vision of equitable, person-centered skin health for all.

Acknowledgments

The authors would like to thank all partners involved in this study–the World Health Organization (WHO), Open University of Catalonia, Kenyan Medical Research Institute, the Kenyan Ministry of Health, and their funders at the Special Programme for Research and Training in Tropical Diseases (TDR). The authors are especially grateful to all FHWs who participated in the study, the health care facilities that hosted the research, and the patients who consented to the use of the WHO Skin Neglected Tropical Diseases app as part of their clinical consultations. Generative artificial intelligence was not used in any portion of the manuscript writing.

Funding

This study was funded by TDR, the Special Programme for Research and Training in Tropical Diseases, and the World Health Organization.

Data Availability

The datasets generated or analyzed during this study are not publicly available, as their primary value lies in the interpretive account developed through thematic analysis, rather than in reuse of raw data. All key findings and interpretations are presented in full within this published paper.

Authors' Contributions

JAR-P conceptualized and oversaw the study and secured project funding. CC was the principal investigator of the assessment study and developed the study protocol. RN served as site principal investigator and, together with EK, coordinated participant identification and recruitment, acting as the primary point of contact for frontline health workers. EEVQ led the qualitative component of the study, including development of the interview and focus group guides. Focus group discussions were facilitated by EEVQ, CC, RN, and DA. Semistructured interviews were conducted by EEVQ, CC, RN, DA, and AFC. EEVQ conducted the thematic analysis, with a subset of transcripts double coded by AB and KO. EEVQ drafted the manuscript. All authors reviewed and approved the final version. The participants did not have a professional or personal relationship with the researchers prior to the study.

Conflicts of Interest

Abstract

Background: Mobile apps and wearable devices may help to facilitate early detection of mental health conditions by providing objective, real-time data to supplement other forms of feedback and diagnoses. Few studies have investigated the acceptability and feasibility of using a mobile app to track survey- and wearable-based data in mental health research in Sub-Saharan Africa.

Objective: This pilot study evaluated the feasibility and acceptability of using a mobile app and wearables to capture mental health–based survey data and passively sensed data among Kenyan health care workers.

Methods: A mixed methods study was conducted among health care workers employed at 4 hospitals in Nairobi, Kenya, over 30 days. A mobile app was used to collect and integrate active (baseline questionnaire and daily mood) and passive (wearable) data. The baseline questionnaire gathered information on sociodemographics, work environment, and mental health assessments on depression, anxiety, personality, early family environment, posttraumatic stress disorder, and substance use. A wearable device was used to gather data on steps, heart rate, and sleep. Qualitative interviews were conducted post trial to gain in-depth insights into participants' experiences during the study.

Results: Fifty-one participants enrolled in the pilot study. They were primarily nurses (47%) and female (70%), with a median (IQR) age of 32 (29-36) years. Attrition over 30 days was low, with only one participant dropping out due to device malfunction, which was a broken screen. Completeness of the baseline survey was high, with participants completing 96.1% of the questions. Further, 58% of the daily mood ratings were completed over the 30 days. For the wearable measures, participants submitted steps, heart rate, and sleep data on 93%, 73%, and 51% of study days, respectively. The proportion of days the wearable was worn for over 10 hours was 63%. Interviews revealed 2 primary themes. The first was intrinsic and extrinsic motivation; participants indicated that they liked having their health metrics tracked and receiving congratulatory messages from the app, encouraging increased step counts. The second theme was technical and usability challenges; 48% (10/21) of the participants reported discomfort wearing the watch while sleeping and challenges with synchronization of data due to the nonautomated nature of the process. Participants suggested additional prompts to remind them to complete the daily mood question.

Conclusions: This pilot study demonstrates the feasibility of deploying mental health surveys, collecting data through wearable devices, and integrating such data within a single mobile platform under real-world infrastructure constraints. Health care workers

in Kenya were willing to provide sensitive information through mental health assessments using a mobile app. To improve adherence, future studies should consider addressing some contextual factors such as daily prompts, enhanced data synchronization methods, and comfort concerns to improve adherence, especially during sleep.

Introduction

Globally, health care workers (HCWs) play a crucial role in the health care system, in support of a wide array of responsibilities from patient care to supporting critical operational functions [1]. Human resources are limited in health care systems located in low- and middle-income countries (LMICs), resulting in strain on the professionals in the system [2]. Additionally, the nature of the work involves exposure to potentially traumatic events which may place HCWs at greater risk for psychological distress [3]. A meta-analysis including HCWs from 50 countries found that 42% reported anxiety symptoms, 33% reported depressive symptoms, and 42% reported insomnia, highlighting the high burden of these mental disorders [4]. In Kenya, similar findings were reported showing HCWs to be at risk of mental disorders such as depression at 32%, anxiety at 36%, and harmful alcohol use at 43.9%, and this was exacerbated during the COVID pandemic [5,6].

Prevention and early treatment of mental health conditions and psychological distress have the potential to reduce the impact of these disorders on the workforce and improve productivity and quality of output [7]. The traditional way of diagnosing mental health conditions is through questionnaires and scorecards during a patient visit [8]. However, point-in-time (eg, during an appointment with a health care provider) and retrospective questionnaires can result in the loss of valuable data informing diagnostic conclusions [9]. There is a growing interest in the use of digital technologies, such as smartphone apps and wearables, to augment traditional mental health care, particularly in LMICs where resources are limited for surveillance, diagnosis, and treatment. These approaches leverage streams of passively collected data captured from personal digital sensors to infer, monitor, and predict changes in health states over time [10-12].

Wearable devices capture objective indicators of sleep, physical activity, and heart rate, and changes in these variables have been closely linked to mental health states. For example, short or fragmented sleep has been associated with depression and anxiety, reduced physical activity has been linked to depressive symptoms, and elevated resting heart rate or reduced heart rate variability can reflect autonomic dysregulation observed in stress-related mood disorders [13-18]. Together, these measures provide real-time, ecological data that complement self-reported questionnaires and supplement longitudinal monitoring of mental health trajectories.

Wearable devices and mobile health (mHealth) technologies have been used in high-income countries to assess mental health indicators in various populations, including medical residents [18]. However, the integration of wearable device information with traditional questionnaires into a data collection platform in Africa has been scant, partly due to the infrastructure cost and limited availability of devices [19]. Despite these limitations, the continued increase in mobile phone access in LMICs such as Kenya provides an opportunity to digitize data collection through mobile apps [20]. In Kenya, studies have been conducted on the use of wearable devices for different health conditions and climate factors, with limited studies focused on mental health factors [21]. Thus, understanding the feasibility and acceptability of these platforms is important in assessing readiness for deployment of digitized platforms for mental health research in countries such as Kenya.

This pilot study evaluated the feasibility and acceptability of using a mobile technology app and wearables to collect both survey-based and passively sensed data among Kenyan HCWs to inform the deployment of a larger mHealth study. The primary focus was on the practical ability to deploy surveys, sustain device wear, and synchronize wearable data through an integrated app under real-world infrastructure constraints.

Methods

Research Design

This study used a sequential explanatory mixed methods approach where we conducted quantitative survey and wearable data collection for 30 days, after which qualitative interviews were completed to provide context to the quantitative outcomes. Our results are reported in line with the CONSORT (Consolidated Standards of Reporting Trials) extension for randomized pilot and feasibility trials (Multimedia Appendix 1) [22].

Study Participants and Sampling Methods

HCWs, including nurses, doctors, psychologists, pharmacists, radiographers, physiotherapists, and nutritionists, were recruited from 4 urban health care facilities in Nairobi, Kenya from July to August 2022 (Table 1). Study inclusion criteria were aged 18 years or older, employment as an HCW, and smartphone ownership.

Table . Description of health care facilities in Nairobi, Kenya[a,b].

Facility	Description
1	A level 5 tertiary private health care facility with 1088 health care workers.
2	A level 6 national referral hospital with 665 health care workers.
3	A level 5 county referral hospital, with 700 health care workers.
4	A level 5 obstetric and delivery referral hospital, with 396 health care workers.

[a]Health care facilities associated with a 30-day mixed methods pilot study focused on the feasibility and acceptability of using a mobile app to track survey- and wearable-based data in mental health research among Kenyan health care workers.

[b]Level 5 facilities are secondary referral hospitals that offer diagnostic and specialized care and more comprehensive medical care. Level 6 facilities are national referral and teaching hospitals.

Recruitment

Recruitment strategies have been previously described [23]. Briefly, in-person sensitization meetings were conducted in study sites. During these sessions, HCWs were informed about the study objectives, duration, and study procedures. Additional recruitment strategies included email blasts, posters, and pamphlets placed around the health care facilities, and snowballing through participants who had already registered. Those interested in participating were invited to complete an online registration form that collected names, work cadre, email addresses, and phone numbers for enrollment. To increase reach, the registration form, along with brochures containing frequently asked questions sheets and QR codes for registering, was circulated in departmental WhatsApp (Meta Platforms) groups, Continuous Medical Education meetings, and virtual sensitization meetings. In total, 356 HCWs expressed interest in the study.

Of these, 60 individuals were randomly selected and stratified by facility using a random number generator. The target sample size for the pilot was n=50; thus, 60 individuals were contacted with an anticipated participation rate of 80%. The randomly selected individuals were contacted by email and invited to enroll in the pilot study within 7 days. Participants enrolled using the MyDataHelps (CareEvolution) mobile app. Within a week, 51 individuals provided informed consent and were enrolled in the study. Qualitative exit interviews were performed at the end of the study, with a subset of participants (n=22) selected through convenience sampling. Participants were recruited from individuals who were readily available and had participated in the broader study, rather than being selected through random sampling. Potential participants were identified based on their availability and willingness to participate in follow-up qualitative interviews. Representation across professional cadres and institutions was desired; however, the availability of participants was a key factor for inclusion due to demanding schedules. Participants were contacted by phone to schedule an appointment to meet face-to-face with the researchers to review the consent form. Of the 22 who were contacted, 1 participant declined to participate in the interviews.

Survey and Wearable Data Collection Procedures

Following study enrollment, participants completed a baseline questionnaire that included information on sociodemographics, work environment, and the following assessments: (1) the Neuroticism, Extraversion, Openness to Experience Five-Factor Inventory to assess domains of personality in 5 areas [24]; (2) Risky Families Questionnaire to assess the degree of physical, mental, and emotional distress experienced in their homes during childhood and adolescence [25]; (3) Generalized Anxiety Disorder-7 to measure anxiety scores [26]; (4) Patient Health Questionnaire-9 to assess symptoms of depression [27]; (5) posttraumatic stress disorder (PTSD) checklist to assess presence and severity of PTSD symptoms [28]; and (6) World Health Organization Alcohol, Smoking and Substance Involvement Screening Test to assess substance use–related health risks and substance use disorders [29].

Following submission of the baseline questionnaire, participants received a Fitbit Inspire 2 (Fitbit Inc) and were instructed to wear the device continuously for the duration of the 30-day study. Participants were instructed on how to use wrist mode, verify that the sleep feature was on, and ensure syncing of the data with the mobile apps. Additionally, participants were advised to charge the device as soon as a low battery notification appeared. The battery life on Fitbit is up to 10 days on a single charge and charges to full in about 1 to 2 hours. Sleep, step count, heart rate, and mood rating were collected daily for 30 days.
